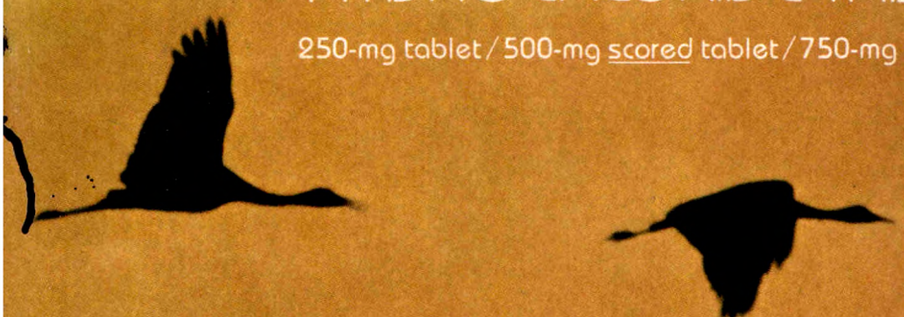
Return to a natural cardiac rhythm

SUSTAINED RELEASE

Procan® SR

(PROCAINAMIDE HYDROCHLORIDE TABLETS)

250-mg tablet / 500-mg scored tablet / 750-mg scored tablet



Enhances the value of oral procainamide for selected cardiac dysrhythmias

With modern sustained-release Procan SR, short duration of effect no longer impedes the usefulness of procainamide for maintenance therapy. A standard medication now assumes greater importance, both in terms of convenience and patient compliance.

Administered half as often as conventional oral procainamide

Wide versatility in cardiac conditions

Can be used concomitantly with digoxin

Ideal maintenance therapy

If in the past you have substituted another medication for maintenance therapy because of compliance problems with conventional oral procainamide, now you can logically turn to the modern oral procainamide.

Procan SR... the original sustained-release oral procainamide

PARKE-DAVIS
Division of Warner-Lambert Company
Morris Plains, New Jersey 07950

Please see next page for brief summary of prescribing information.

Procan® SR
(procainamide hydrochloride tablets)
SUSTAINED RELEASE

Before prescribing, please see full prescribing information.
A Brief Summary follows.

The prolonged administration of procainamide often leads to the development of a positive antinuclear antibody (ANA) test with or without symptoms of lupus erythematosus-like syndrome. If a positive ANA titer develops, the benefit/risk ratio related to continued procainamide therapy should be assessed. This may necessitate consideration of alternative antiarrhythmic therapy.

INDICATIONS AND USAGE: Oral procainamide is indicated in the treatment of premature ventricular contractions and ventricular tachycardia, atrial fibrillation, and paroxysmal atrial tachycardia.

CONTRAINDICATIONS: It has been suggested that procainamide be contraindicated in patients with myasthenia gravis. Hypersensitivity to the drug is an absolute contraindication; in this connection, cross-sensitivity to procaine and related drugs must be borne in mind. Procainamide should not be administered to patients with complete atrioventricular heart block. Procainamide is also contraindicated in cases of second-degree and third-degree A-V block unless an electrical pacemaker is operative.

PRECAUTIONS: General —During administration of the drug, evidence of untoward myocardial responses should be carefully watched for in all patients. In the presence of an abnormal myocardium, procainamide may at times produce untoward responses. In atrial fibrillation or flutter, the ventricular rate may increase suddenly as the atrial rate is slowed. Adequate digitalization reduces, but does not abolish, this danger. If myocardial damage exists, ventricular tachysystole is particularly hazardous. Correction of atrial fibrillation, with resultant forceful contractions of the atrium, may cause a dislodgement of mural thrombi and produce an embolic episode. However, it has been suggested that in a patient who is already discharging emboli, procainamide is more likely to stop than to aggravate the process.

Attempts to adjust the heart rate in a patient who has developed ventricular tachycardia during an occlusive coronary episode should be carried out with extreme caution. Caution is also required in marked disturbances of atrioventricular conduction such as A-V block, bundle branch block, or severe digitalis intoxication, where the use of procainamide may result in additional depression of conduction and ventricular asystole or fibrillation.

Because patients with severe organic heart disease and ventricular tachycardia may also have complete heart block, which is difficult to diagnose under these circumstances, this complication should always be kept in mind when treating ventricular arrhythmias with procainamide. If the ventricular rate is significantly slowed by procainamide without attainment of regular atrioventricular conduction, the drug should be stopped and the patient reevaluated since asystole may result under these circumstances.

In patients receiving normal dosage, but who have both liver and kidney disease, symptoms of overdosage (principally ventricular tachycardia and severe hypotension) may occur due to drug accumulation.

Instances of a syndrome resembling lupus erythematosus have been reported in connection with maintenance procainamide therapy. The mechanism of this syndrome is uncertain. Polyarthralgia, arthritis, and pleuritic pain are common symptoms; to a lesser extent, fever, myalgia, skin lesions, pleural effusion, and pericarditis may occur. Rare cases of thrombocytopenia or Coombs-positive hemolytic anemia have been reported which may be related to this syndrome.

Laboratory Tests—Patients receiving procainamide for extended periods of time, or in whom symptoms suggestive of a lupus-like reaction appear, should have antinuclear antibody titers measured at regular intervals. The drug should be discontinued if there is a rising titer (antinuclear antibody) or clinical symptoms of LE appear. The LE syndrome may be reversible upon discontinuation of the drug. If discontinuation of the drug does not cause remission of the symptoms, steroid therapy may be effective. If the syndrome develops in a patient with recurrent life-threatening arrhythmias not controllable by other antiarrhythmic agents, steroid suppressive therapy may be used concomitantly with procainamide. It is recommended that tests for lupus erythematosus be carried out at regular intervals in patients receiving maintenance procainamide therapy.

Routine blood counts are advisable during maintenance procainamide therapy.

ADVERSE REACTIONS: Agranulocytosis has occasionally followed the repeated use of the drug, and deaths have occurred. Therefore, routine blood counts are advisable during maintenance procainamide therapy. The patient should be instructed to report any soreness of the mouth, throat, or gums, unexplained fever, or any symptoms of upper respiratory tract infection. If any of these should occur, and leukocyte counts indicate cellular depression, procainamide therapy should be discontinued and appropriate treatment should be instituted immediately.

Hypersensitivity reactions, such as angioneurotic edema and maculopapular rash have also occurred.

A syndrome resembling lupus erythematosus has been reported (see PRECAUTIONS).

Hypotension following oral administration is rare.

Large oral doses of procainamide may sometimes produce anorexia, nausea, urticaria, and/or pruritus.

Reactions consisting of fever and chills have also been reported, including a case with fever and chills plus nausea, vomiting, abdominal pain, acute hepatomegaly, and a rise in serum glutamic oxaloacetic transaminase following single doses of the drug. Bitter taste, diarrhea, weakness, mental depression, giddiness, and psychosis with hallucinations have been reported. The possibility of such untoward effects should be borne in mind.

DOSAGE AND ADMINISTRATION: Procan SR (procainamide hydrochloride) tablets are a sustained-release product form. The duration of action of procainamide hydrochloride supplied in this sustained-release product form allows dosing at intervals of every six hours instead of the more frequent every-three-hour dosing interval required for standard preparations of oral procainamide hydrochloride. The convenient six-hour dosing schedule may encourage patient compliance.

Ventricular tachycardia—Treatment with standard procainamide hydrochloride is recommended until the tachycardia is interrupted or the limit of tolerance is reached. Maintenance may then be continued with Procan SR.

The suggested dosage is as follows: An initial dose of 1 g of standard procainamide hydrochloride followed thereafter by a total daily dose of 50 mg/kg of body weight given at three hour intervals. The suggested oral dosage for premature ventricular contractions is 50 mg/kg of body weight daily given in divided doses at three-hour intervals.

The suggested maintenance dosage of Procan SR is 50 mg/kg of body weight daily given in divided doses at six-hour intervals.

Although the dosage for each patient must be determined on an individual basis, the following may be used as a guide for providing the total daily dosage: patients weighing less than 55 kg (120 lb), 0.5 g every six hours; patients weighing between 55 and 91 kg (120 and 200 lb), 0.75 g every six hours; and patients weighing over 91 kg (200 lb), 1 g every six hours.

Atrial fibrillation and paroxysmal atrial tachycardia—Treatment with standard procainamide hydrochloride is recommended until the arrhythmia is interrupted or the limit of tolerance is reached. Maintenance may then be continued with Procan SR.

The suggested dosage is as follows. An initial dose of 1.25 g of standard procainamide hydrochloride may be followed in one hour by 0.75 g if there have been no electrocardiographic changes. Standard procainamide hydrochloride may then be given at a dose of 0.5 to 1 g every two hours until interruption of the arrhythmia or the tolerance limit is reached.

The suggested maintenance dosage for Procan SR is 1 g every six hours.

If procainamide therapy is continued for appreciable periods, electrocardiograms should be made occasionally to determine the need for the drug.

HOW SUPPLIED: Procan SR 250 mg (green, film-coated tablet. P-D 202) is available in bottles of 100 (N 0071-0202-24) and in unit-dose packages of 100 (10 strips of 10 tablets each) (N 0071-0202-40). Each sustained-release tablet contains 250 mg procainamide hydrochloride.

Procan SR 500 mg (yellow, scored, film-coated tablet. P-D 204) is available in bottles of 100 (N 0071-0204-24) and in unit-dose packages of 100 (10 strips of 10 tablets each) (N 0071-0204-40). Each sustained-release tablet contains 500 mg procainamide hydrochloride.

Procan SR 750 mg (orange, scored, film-coated tablet. P-D 205) is available in bottles of 100 (N 0071-0205-24) and in unit-dose packages of 100 (10 strips of 10 tablets each) (N 0071-0205-40). Each sustained-release tablet contains 750 mg procainamide hydrochloride.

Storage—Protect from moisture. Store bottles below 86° F (30° C). Store unit-dose packages at controlled room temperature, 59°-86° F (15°-30° C).

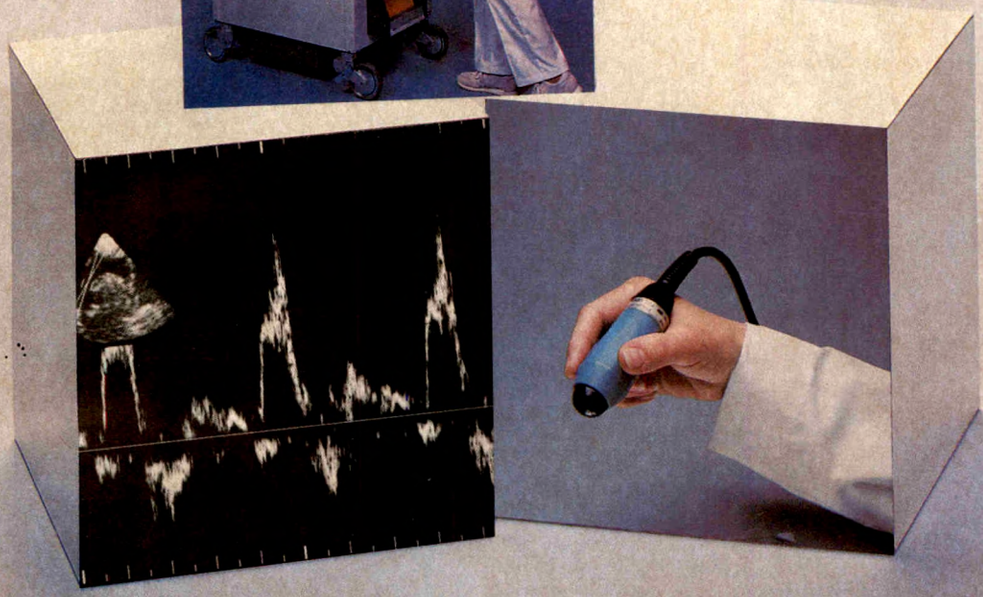
Build your diagnostic confidence on your new ND2600. . . year after year.



ITH UNMATCHED IMAGE QUALITY. The same image quality Biosound has perfected and maintained for many years becomes immediately apparent with the clear, crisp echo data shown on the ND2600. 2D and M-Mode image that is a result of fully integrated system design assures performance consistency from innovative probe technology to high resolution video display.

WITH NORMALIZED™ DOPPLER. Localization of regurgitant jets, quantitation of valvular stenosis and vascular duplex scanning are three major clinical reasons to upgrade your ultrasound procedure to include Doppler. Pulsed and CW Doppler with a number of operator selectable display formats are available with the new ND2600. Superior spectral display of blood velocities and 200 per second Doppler sample rate are combined in an easy to use system insuring exceptional quantitative Doppler information for all cardiovascular procedures.

WITH COMPACTNESS AND MOBILITY. The new ND2600 is the smallest full featured cardiovascular 2D echo system you can find. A truly integrated design provides for every option you need. Now and in the future. The low profile system allows unparalleled ease of movement. It represents the ultimate in operator convenience from versatile multilevel alphanumeric keyboard to unique display and control panel that swivels ±135 degrees from center. Optimized for left or right hand scanning.

WITH POWERFUL ADVANCED ARRAY PROCESS computer controlled software based ND260 microprocessor and exclusive patented ar gives more computer power than conventi based systems. Assures 10 to 100 times faste analysis. Multiple measurements can be m data accurately. Up to 26 per image. 2D, M- Doppler flow measurements can be easily performed.

WITH A COMPLETELY UPGRADEABLE SYSTEM expansion of capability instead of size. ND restricted by hardware configuration. The s fully integrated design assures no change i system size regardless of the options you ac

WITH THE BIOSOUND COMMITMENT to conti innovation, solid support and thorough use Continue to build your diagnostic confider year. Clinically proven technology combin dedicated direct field service staff and an customer training and support program ar benefits that come with an ND2600 system. yet, talk to a Biosound user. We'd like to sh Biosound ND2600 will be the only Duplex S to purchase for a long time.

The only system you'll have to purchase for a long time.

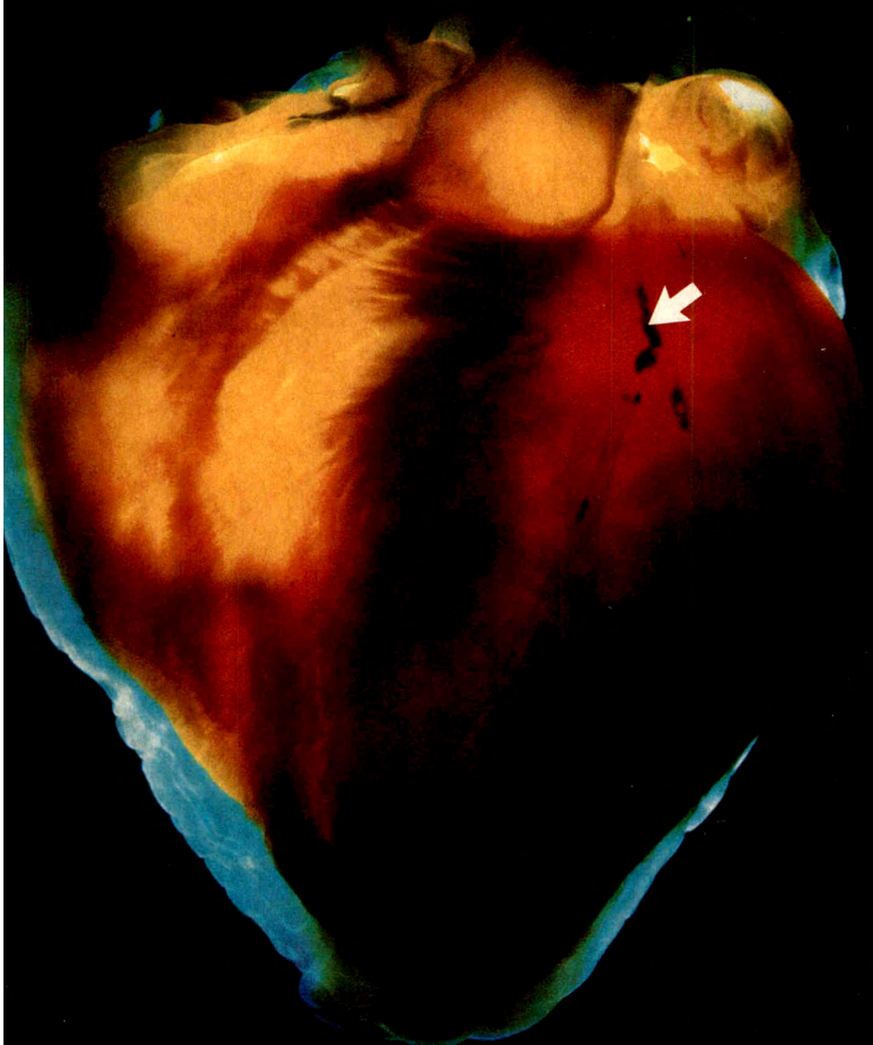
WORK IN PROGRESS

from a university collaboration with
Smith Kline &French Laboratories
a leader in cardiovascular research



Calcified atherosclerotic plaques (arrow) are visible in branches of the left anterior descending artery (LAD) in this infrared photograph of a transilluminated cleared human heart. The epicardial fat appears blue or green, the atria and right ventricular wall appear yellow and the left ventricular myocardium is seen as red.

This extraordinary photographic technique enables investigators to study atherosclerotic plaque without opening or dissecting the vessels.

Membrane Stabilizing Activity: Working to Control Arrhythmias

The Stabilizer:

QUINAGLUTE® DURA-TABS®

(quinidine gluconate) SUSTAINED-RELEASE TABLETS 324 mg

Stable plasma levels: a factor in maintaining stable cardiac rhythm

Easy-to-remember q12h dosage* promotes compliance

Fewer GI side effects than quinidine sulfate†

*Some patients may require more frequent (TID) dosing.

†Podrid P.J: *Patient Care* 1981;15:100-132.

Please turn page for brief summary of prescribing information.

QUINAGLUTE®(quinidine gluconate) DURA-TABS®
INDICATIONS AND USAGE: Quinaglute (quinidine gluconate) Dura-Tabs are indicated in the prevention and/or treatment of:
1. Ventricular arrhythmias: Premature ventricular contractions, ventricular tachycardia (when not associated with complete heartblock).
2. Junctional (nodal) arrhythmias: A-V junctional premature complexes, paroxysmal junctional tachycardia. **3. Supraventricular (atrial) arrhythmias:** Premature atrial contractions, paroxysmal atrial tachycardia, atrial flutter, atrial fibrillation (chronic and paroxysmal).
CONTRAINDICATIONS: 1. Idiosyncrasy or hypersensitivity to quinidine. 2. Complete A-V block. 3. Complete bundle branch block or other severe intraventricular conduction defects, especially those exhibiting a marked grade of QRS widening. 4. Digitalis intoxication manifested by A-V conduction disorders. 5. Myasthenia gravis. 6. Aberrant impulses and abnormal rhythms due to escape mechanisms.
WARNINGS: 1. In the treatment of atrial flutter, reversion to sinus rhythm may be preceded by a progressive reduction in the degree of A-V block to a 1:1 ratio resulting in an extremely rapid ventricular rate. This possible hazard may be reduced by digitalization prior to administration of quinidine.
2. Recent reports indicate that plasma concentrations of digoxin increase and may even double when quinidine is administered concurrently. Patients on concomitant therapy should be carefully monitored. Reduction of digoxin dosage may have to be considered.
3. Manifestations of quinidine cardiotoxicity such as excessive prolongation of the Q-T interval, widening of the QRS complex and ventricular tachyarrhythmias mandate immediate discontinuation of the drug and/or close clinical and electrocardiographic monitoring.
4. In susceptible individuals, such as those with marginally compensated cardiovascular disease, quinidine may produce clinically important depression of cardiac function such as hypotension, bradycardia, or heartblock. Quinidine therapy should be carefully monitored in such individuals.
5. Quinidine should be used with extreme caution in patients with incomplete A-V block since complete block and asystole may be produced. Quinidine may cause abnormalities of cardiac rhythm in digitalized patients and therefore should be used with caution in the presence of digitalis intoxication. 6. Quinidine should be used with caution in patients exhibiting renal, cardiac or hepatic insufficiency because of potential accumulation of quinidine in plasma leading to toxicity.
7. Patients taking quinidine occasionally have syncopal episodes which usually result from ventricular tachycardia or fibrillation. This syndrome has not been shown to be related to dose or plasma levels. Syncopal episodes frequently terminate spontaneously or in response to treatment, but sometimes are fatal.
8. A few cases of hepatotoxicity, including granulomatous hepatitis, due to quinidine hypersensitivity have been reported in patients taking quinidine. Unexplained fever and/or elevation of hepatic enzymes, particularly in the early stages of therapy, warrant consideration of possible hepatotoxicity. Monitoring liver function during the first 4-8 weeks should be considered. Cessation of quinidine in these cases usually results in the disappearance of toxicity.
PRECAUTIONS: General: The precautions to be observed include all those applicable to quinidine. A preliminary test dose of a single tablet of quinidine sulfate may be administered to determine if the patient has an idiosyncrasy to quinidine. Hypersensitivity to quinidine, although rare, should constantly be considered, especially during the first weeks of therapy. Hospitalization for close clinical observation, electrocardiographic monitoring, and possible determination of plasma quinidine levels is indicated when large doses are used, or with patients who present an increased risk.
Information for Patients: As with all solid oral medications, Quinaglute (quinidine gluconate) Dura-Tabs (sustained-release tablets) should be taken with an adequate amount of fluid, preferably in an upright position, to facilitate swallowing.

Drug Interactions: *Drug*	*Effect*
Quinidine with anticholinergic drugs	Additive vagolytic effect
Quinidine with cholinergic drugs	Antagonism of cholinergic effects
Quinidine with carbonic anhydrase inhibitors, sodium bicarbonate, thiazide diuretics	Alkalinization of urine resulting in decreased excretion of quinidine
Quinidine with coumarin anticoagulants	Reduction of clotting factor concentrations
Quinidine with tubocurare, succinylcholine and decamethonium	Potentiation of neuromuscular blockade
Quinidine with phenothiazines and reserpine	Additive cardiac depressive effects
Quinidine with hepatic enzyme-inducing drugs (phenobarbital, phenytoin, rifampin)	Decreased plasma half-life of quinidine
Quinidine with digoxin	Increased plasma concentrations of digoxin (see WARNINGS)

Carcinogenesis, Mutagenesis and Impairment of Fertility: Long-term studies in animals have not been performed to evaluate the carcinogenic potential of quinidine. There is currently no evidence of quinidine-induced mutagenesis or impairment of fertility.
Pregnancy: *Teratogenic Effects:* Pregnancy Category C. Animal reproduction studies have not been conducted with quinidine. There are no adequate and well-controlled studies in pregnant women. Quinaglute (quinidine gluconate) Dura-Tabs should be given to a pregnant woman only if clearly needed. *Nonteratogenic Effects:* Like quinine, quinidine has been reported to have oxytocic properties. The significance of this property in the clinical setting has not been established.
Nursing Mothers: Caution should be exercised when Quinaglute (quinidine gluconate) Dura-Tabs are administered to a nursing woman due to passage of the drug into breast milk.
Pediatric Use: There are no adequate and well-controlled studies establishing the safety and effectiveness of Quinaglute (quinidine gluconate) Dura-Tabs in children.
ADVERSE REACTIONS: Symptoms of cinchonism, ringing in ears, headache, nausea, and/or disturbed vision may appear in sensitive patients after a single dose of the drug. The most frequently encountered side effects to quinidine are gastrointestinal in nature. These gastrointestinal effects include nausea, vomiting, abdominal pain and diarrhea.
Less frequently encountered adverse reactions:
Cardiovascular: Widening of QRS complex, cardiac asystole, ventricular ectopic beats, idioventricular rhythms including ventricular tachycardia and fibrillation, paradoxical tachycardia, arterial embolism and hypotension.
Hematologic: Acute hemolytic anemia, hypoprothrombinemia, thrombocytopenia (purpura), agranulocytosis.
Central Nervous System: Headache, fever, vertigo, apprehension, excitement, confusion, delirium and syncope, disturbed hearing (tinnitus, decreased auditory acuity), disturbed vision (mydriasis, blurred vision, disturbed color perception, reduced vision field, photophobia, diplopia, night blindness, scotomata), optic neuritis.
Dermatologic: Rash, cutaneous flushing with intense pruritus, urticaria. Photosensitivity has also been reported.
Hypersensitivity Reactions: Angioedema, acute asthmatic episode, vascular collapse, respiratory arrest, hepatic toxicity including granulomatous hepatitis (see WARNINGS). Although extremely rare, there have also been reports of lupus erythematosus in patients taking quinidine. A positive association with quinidine therapy has not been established.
See package insert for full information.

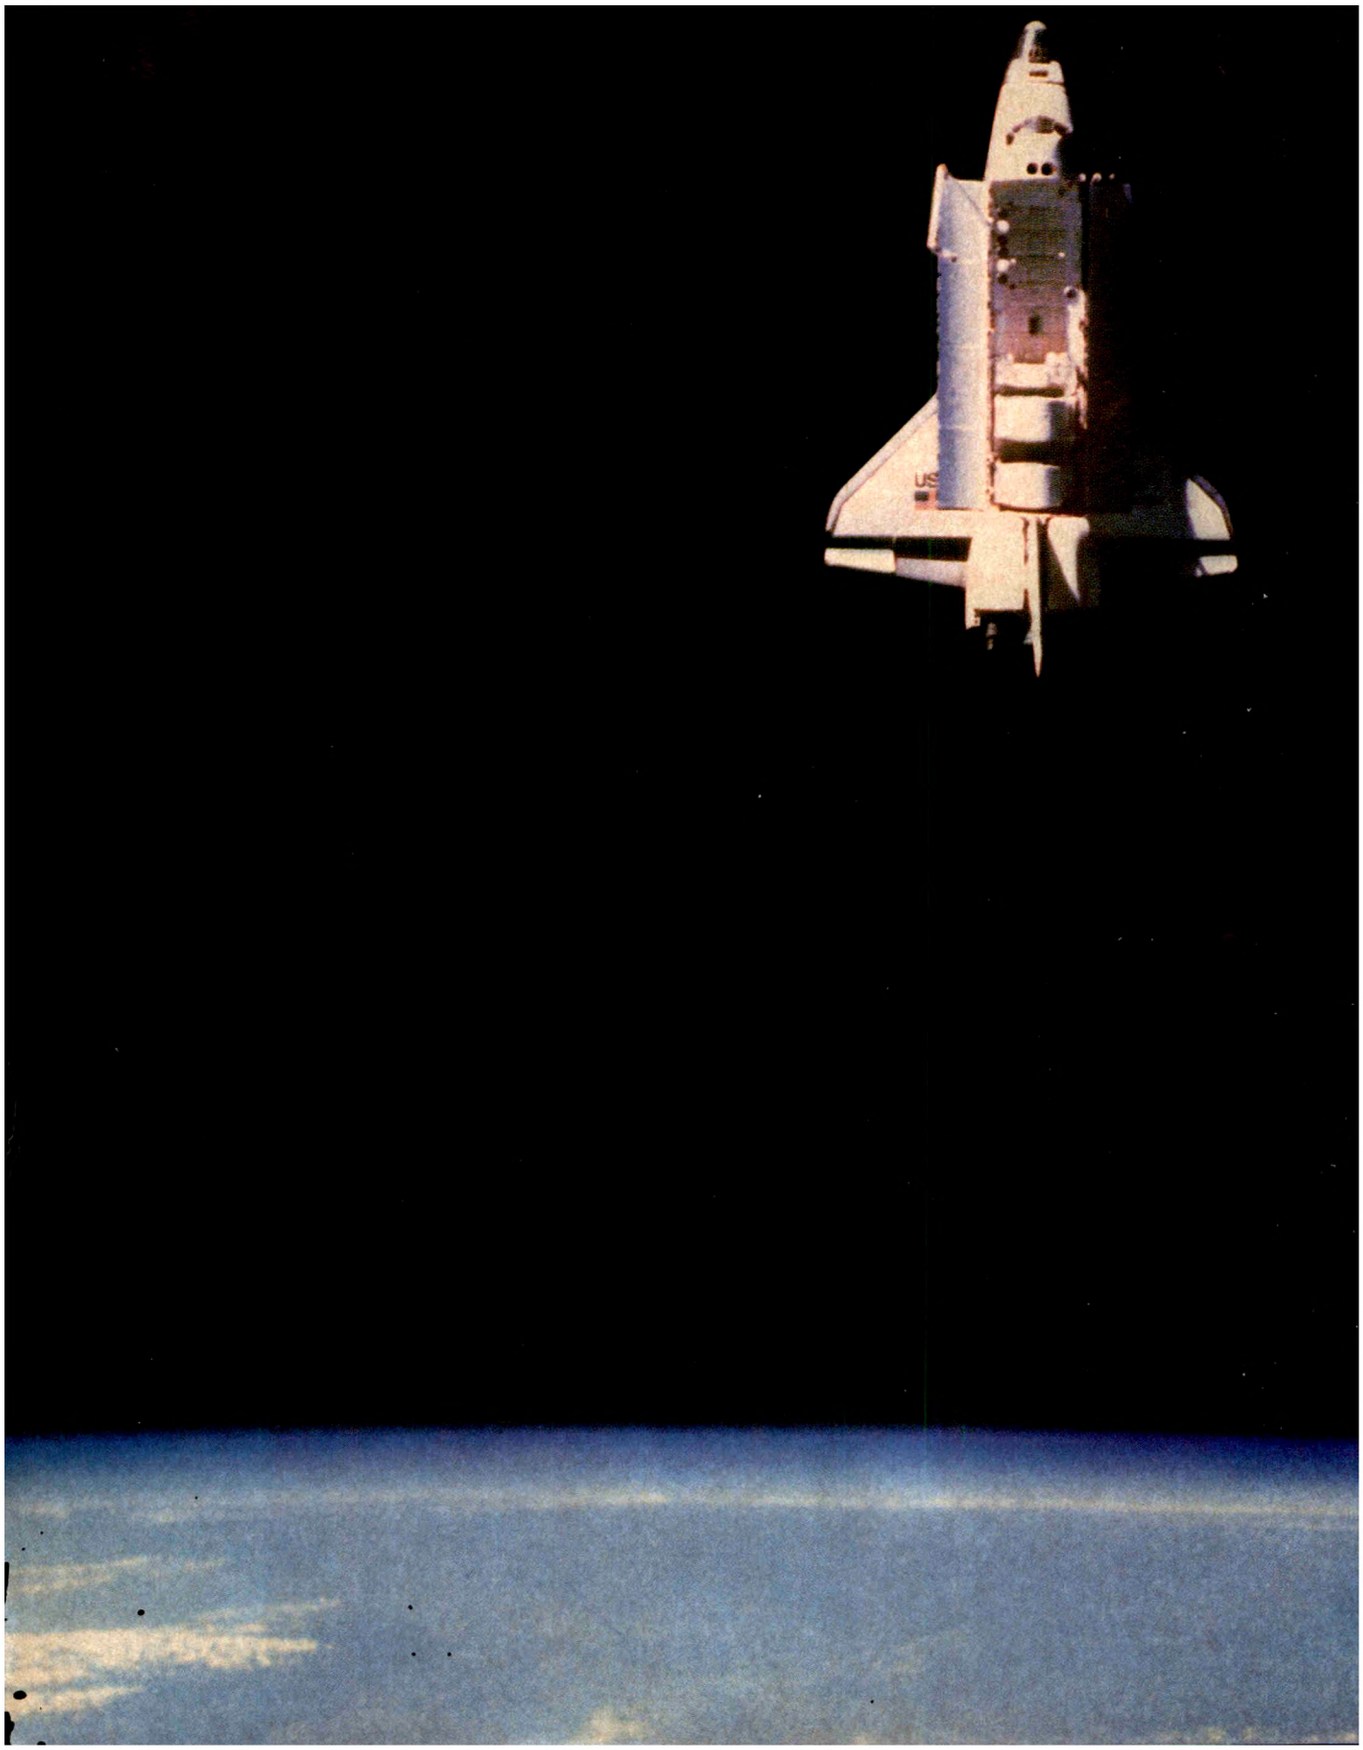
523-501 Issued: January 1983



In most cases, our field service engineers are never more than 50 miles away.

There are still a few places an HP field service engineer can't reach in an hour. So when NASA chose the **Hewlett-Packard ultrasound** imaging system for Spacelab 4, they chose it for its reliability. You don't get second chances when you're hundreds of miles from earth.

Reliability. Hewlett-Packard's pretesting practically guarantees it. Our tests exceed even the toughest NASA requirements. And HP ultrasound's remote diagnostic capabilities and self-testing features make system evaluation simple, comprehensive and dependable. Our track record here on earth proves it—99% average uptime in existing hospital installations.

Your ultrasound system will never have to survive launch, orbit and reentry. But it will have to survive the even tougher tests of cost-effectiveness, upgradeability, image quality and long-term reliability. Achieving all this may seem an astronomical task for some. For HP, the achievement is a fact of life.

To find out more about the complete line of Hewlett-Packard ultrasound imaging systems, write to: Inquiries Manager, Hewlett-Packard, Dept. A18, 3000 Minuteman Road, Andover, MA 01810. Or call your local HP sales office listed in the White Pages.

Hewlett-Packard offers two superior cardiac imaging systems with Doppler capabilities: the HP77020AC phased array imaging system and the HP77065AC mechanical imaging system. Both provide incomparable image quality and reliability.

We want you to have the answers

Visken®

5-mg and 10-mg Tablets

(pindolol)

Before prescribing or administering, see package circular for full product information. The following is a brief summary.

INDICATIONS AND USAGE
Visken® (pindolol) is indicated in the management of hypertension. It may be used alone or concomitantly with other antihypertensive agents, particularly with a thiazide type diuretic.

CONTRAINDICATIONS
Visken (pindolol) is contraindicated in: 1) bronchial asthma; 2) overt cardiac failure; 3) cardiogenic shock; 4) second and third degree heart block; 5) severe bradycardia; (see Warnings).

WARNINGS
Cardiac Failure: Sympathetic stimulation may be a vital component supporting circulatory function in patients with congestive heart failure, and its inhibition by beta-blockade may precipitate more severe failure. Although beta-blockers should be avoided in overt congestive heart failure, if necessary, Visken (pindolol) can be used with caution in patients with a history of failure who are well-compensated, usually with digitalis and diuretics. Beta-adrenergic blocking agents do not abolish the inotropic action of digitalis on heart muscle.

In Patients Without A History of Cardiac Failure: In patients with latent cardiac insufficiency, continued depression of the myocardium with beta-blocking agents over a period of time can in some cases lead to cardiac failure. At the first sign or symptom of impending cardiac failure, patients should be fully digitalized and/or be given a diuretic, and the response observed closely. If cardiac failure continues, despite adequate digitalization and diuretic, Visken (pindolol) therapy should be withdrawn (gradually if possible).

Exacerbation of Ischemic Heart Disease Following Abrupt Withdrawal: Hypersensitivity to catecholamines has been observed in patients withdrawn from beta-blocker therapy; exacerbation of angina and, in some cases, myocardial infarction have occurred after *abrupt* discontinuation of such therapy. When discontinuing chronically administered Visken (pindolol), particularly in patients with ischemic heart disease, the dosage should be gradually reduced over a period of one to two weeks and the patient should be carefully monitored. If angina markedly worsens or acute coronary insufficiency develops, Visken (pindolol) administration should be reinstituted promptly, at least temporarily, and other measures appropriate for the management of unstable angina should be taken. Patients should be warned against interruption or discontinuation of therapy without the physician's advice. Because coronary artery disease is common and may be unrecognized, it may be prudent not to discontinue Visken (pindolol) therapy abruptly even in patients treated only for hypertension.

Nonallergic Bronchospasm (e.g., chronic bronchitis, emphysema)—Patients with Bronchospastic Diseases Should in General Not Receive Beta-Blockers: Visken (pindolol) should be administered with caution since it may block bronchodilation produced by endogenous or exogenous catecholamine stimulation of $beta_2$ receptors.

Major Surgery: Because beta blockade impairs the ability of the heart to respond to reflex stimuli and may increase the risks of general anesthesia and surgical procedures, resulting in protracted hypotension or low cardiac output, it has generally been suggested that such therapy should be withdrawn several days prior to surgery. Recognition of the increased sensitivity to catecholamines of patients recently withdrawn from beta-blocker therapy, however, has made this recommendation controversial. If possible, beta-blockers should be withdrawn well before surgery takes place. In the event of emergency surgery, the anesthesiologist should be informed that the patient is on beta-blocker therapy. The effects of Visken® (pindolol) can be reversed by administration of beta-receptor agonists such as isoproterenol, dopamine, dobutamine, or levarterenol. Difficulty in restarting and maintaining the heart beat has also been reported with beta-adrenergic receptor blocking agents.

Diabetes and Hypoglycemia: Beta-adrenergic blockade may prevent the appearance of premonitory signs and symptoms (e.g., tachycardia and blood pressure changes) of acute hypoglycemia. This is especially important with labile diabetics. Beta-blockade also reduces the release of insulin in response to hyperglycemia; therefore, it may be necessary to adjust the dose of antidiabetic drugs.

Thyrotoxicosis: Beta-adrenergic blockade may mask certain clinical signs (e.g., tachycardia) of hyperthyroidism. Patients suspected of developing thyrotoxicosis should be managed carefully to avoid abrupt withdrawal of beta-blockade which might precipitate a thyroid crisis.

PRECAUTIONS
Impaired Renal or Hepatic Function: Beta-blocking agents should be used with caution in patients with impaired hepatic or renal function. Poor renal function has only minor effects on Visken (pindolol) clearance, but poor hepatic function may cause blood levels of Visken (pindolol) to increase substantially.

Information for Patients: Patients, especially those with evidence of coronary artery insufficiency, should be warned against interruption or discontinuation of Visken (pindolol) therapy without the physician's advice. Although cardiac failure rarely occurs in properly selected patients, patients being treated with beta-adrenergic blocking agents should be advised to consult the physician at the first sign or symptom of impending failure.

Drug Interactions: Catecholamine-depleting drugs (e.g., reserpine) may have an additive effect when given with beta-blocking agents. Patients receiving Visken (pindolol) plus a catecholamine depleting agent should, therefore, be closely observed for evidence of hypotension and/or marked bradycardia which may produce vertigo, syncope, or postural hypotension.

Visken (pindolol) has been used with a variety of antihypertensive agents, including hydrochlorothiazide, hydralazine, and guanethidine without unexpected adverse interactions.

Carcinogenesis, Mutagenesis, Impairment of Fertility: In chronic oral toxicologic studies (one to two years) in mice, rats, and dogs, Visken (pindolol) did not produce any significant toxic effects. In two-year oral carcinogenicity studies in rats and mice in doses as high as 59 mg/kg/day and 124 mg/kg/day (50 and 100 times the maximum recommended human dose), respectively, Visken (pindolol) did not produce any neoplastic, preneoplastic, or nonneoplastic pathologic lesions. In fertility and general reproductive performance studies in rats, Visken (pindolol) caused no adverse effects at a dose of 10 mg/kg.

In the male fertility and general reproductive performance test in rats, definite toxicity characterized by mortality and decreased weight gain was observed in the group given 100 mg/ kg/day. At 30 mg/kg/day, decreased mating was associated with testicular atrophy and/or decreased spermatogenesis. This response is not clearly drug related, however, as there was no dose response relationship within this experiment and no similar effect on testes of rats administered Visken (pindolol) as a dietary admixture for 104 weeks. There appeared to be an increase in prenatal mortality in males given 100 mg/kg but development of offspring was not impaired.

In females administered Visken (pindolol) prior to mating through day 21 of lactation, mating behavior was decreased at 100 mg/kg and 30 mg/kg. At these dosages there also was increased mortality of offspring. Prenatal mortality was increased at 10 mg/kg but there was not a clear dose response relationship in this experiment. There was an increased resorption rate at 100 mg/kg observed in females necropsied on the 15th day of gestation.

Pregnancy—Category B: Studies in rats and rabbits exceeding 100 times the maximum recommended human doses, revealed no embryotoxicity or teratogenicity. Since there are no adequate and well-controlled studies in pregnant women, and since animal reproduction studies are not always predictive of human response, Visken (pindolol), as with any drug, should be employed during pregnancy only if the potential benefit justifies the potential risk to the fetus.

Nursing Mothers: Since Visken (pindolol) is secreted in human milk, nursing should not be undertaken by mothers receiving the drug.

Pediatric Use: Safety and effectiveness in children have not been established.

CLINICAL LABORATORY
Minor persistent elevations in serum transaminases (SGOT, SGPT) have been noted in 7% of patients during Visken (pindolol) administration, but progressive elevations were not observed and liver injury has not been reported in the medical literature over a ten (10) year period of marketing. Alkaline phosphatase, lactic acid dehydrogenase (LDH) and uric acid are also elevated on rare occasions. The significance of these findings is unknown.

ADVERSE REACTIONS
Most adverse reactions have been mild. The incidences listed in the following table are derived from 12 week comparative double-blind, parallel design trials in hypertensive patients given Visken (pindolol) as monotherapy, given various active control drugs as monotherapy, or given placebo. Data for Visken (pindolol) and the positive controls were pooled from several trials because no striking differences were seen in the individual studies, with one exception. The frequency of edema was noticeably higher in positive control trials (16% Visken (pindolol) vs 9% positive control) than in placebo controlled trials (6% Visken (pindolol) vs 3% placebo). The table includes adverse reactions reported in greater than 2% of Visken (pindolol) patients and other selected important reactions.

	Total (Volunteered and Elicited)		
Body System/ Adverse Reaction	Visken (pindolol) (N = 322) %	Active controls* (N = 188) %	Placebo (N = 78) %

* Active Controls: Patients received either propranolol, α-methyldopa or a diuretic (hydrochlorothiazide or chlorthalidone).

More than 7 million patient-years of experience

The following selected (potentially important) adverse reactions were seen in 2% or fewer patients and their relationship to Visken (pindolol) is uncertain. AUTONOMIC NERVOUS SYSTEM: hyperhidrosis; CARDIOVASCULAR: bradycardia, claudication, cold extremities, heart block, hypotension, syncope, tachycardia; GASTROINTESTINAL: diarrhea, vomiting; RESPIRATORY: wheezing; UROGENITAL: impotence, pollakiuria; MISCELLANEOUS: eye discomfort or burning eyes.

POTENTIAL ADVERSE EFFECTS
In addition, other adverse effects not listed above have been reported with other beta-adrenergic blocking agents and should be considered potential adverse effects of Visken (pindolol).

Central Nervous System: Reversible mental depression progressing to catatonia; an acute reversible syndrome characterized by disorientation for time and place, short-term memory loss, emotional lability, slightly clouded sensorium, and decreased performance on neuropsychometrics.

Cardiovascular: Intensification of AV block. See CONTRAINDICATIONS.

Allergic: Erythematous rash; fever combined with aching and sore throat; laryngospasm; respiratory distress.

Hematologic: Agranulocytosis; thrombocytopenic and non-thrombocytopenic purpura.

Gastrointenstinal: Mesenteric arterial thrombosis; ischemic colitis.

Miscellaneous: Reversible alopecia; Peyronie's disease.

The oculomucocutaneous syndrome associated with the beta-blocker practolol has not been reported with Visken (pindolol) during investigational use and extensive foreign experience amounting to over 4 million patient-years.

OVERDOSAGE
No specific information on emergency treatment of overdosage is available. Therefore, on the basis of the pharmacologic actions of Visken (pindolol), the following general measures should be employed as appropriate in addition to gastric lavage:

Excessive Bradycardia: administer atropine; if there is no response to vagal blockade, administer isoproterenol cautiously.

Cardiac Failure: digitalize the patient and/or administer diuretic. It has been reported that glucagon may be useful in this situation.

Hypotension: administer vasopressors, e.g., epinephrine or levarterenol, with serial monitoring of blood pressure. (There is evidence that epinephrine may be the drug of choice.)

Bronchospasm: administer a $beta_2$ stimulating agent such as isoproterenol and/or a theophylline derivative.

A case of an acute overdosage has been reported with an intake of 500 mg of Visken (pindolol) by a hypertensive patient. Blood pressure increased and heart rate was ≥80 beat/min. Recovery was uneventful. In another case 250 mg of Visken (pindolol) was taken with 150 mg diazepam and 50 mg nitrazepam, producing coma and hypotension. The patient recovered in 24 hours.

DOSAGE AND ADMINISTRATION
The dosage of Visken (pindolol) should be individualized. The recommended initial dose of Visken (pindolol) is 5 mg b.i.d. alone or in combination with other antihypertensive agents. An antihypertensive response usually occurs within the first week of treatment. Maximal response, however, may take as long as or occasionally longer than two weeks. If a satisfactory reduction in blood pressure does not occur within 3-4 weeks, the dose may be adjusted in increments of 10 mg per day at these intervals up to a maximum of 60 mg per day.

HOW SUPPLIED
White, round, scored tablets: 5 mg and 10 mg, packages of 100. 5 mg tablets embossed "VISKEN 5" on one side, and "78-111" and scored on other side (NDC 0078-0111-05). 10 mg tablets embossed "VISKEN 10" on one side, and "78-73" and scored on other side (NDC 0078-0073-05).

CORONARY HEART DISEASE

1 **Baseline Rest Electrocardiographic Abnormalities, Antihypertensive Treatment, and Mortality in the Multiple Risk Factor Intervention Trial**

MULTIPLE RISK FACTOR INTERVENTION TRIAL RESEARCH GROUP

This report presents further analyses pertaining to a previously reported adverse mortality trend in a subgroup of participants in the Multiple Risk Factor Intervention Trial. The adjusted coronary artery disease (CAD) mortality rate was 67% higher in hypertensive men in the special-intervention (SI) group with baseline electrocardiographic abnormalities at rest than in corresponding men in the usual-care (UC) group. Abnormalities were primarily R- or ST-T-wave changes. The higher CAD mortality rate in the SI group was manifested chiefly as sudden death within 1 hour. Men in the SI group with electrocardiographic abnormalities at rest who had been given diuretic drugs (hydrochlorothiazide or chlorthalidone) had a 3-fold higher CAD mortality rate than those not given diuretic drugs. This increased relative risk (diuretics/no diuretics) was not seen among SI men with a normal electrocardiogram at rest nor in the UC group. No relation with diuretic dose or hypokalemia was found.

16 **Exercise Electrocardiogram and Coronary Heart Disease Mortality in the Multiple Risk Factor Intervention Trial**

MULTIPLE RISK FACTOR INTERVENTION TRIAL RESEARCH GROUP

The Multiple Risk Factor Intervention Trial, a primary prevention trial, revealed a 7% lower coronary heart disease (CAD) mortality rate (nonsignificant) in the group randomized to special intervention (SI) to reduce blood cholesterol levels, diastolic blood pressure, and cigarette smoking, compared with a group assigned to usual care (UC). In the UC group the 12% of men with an abnormal ST depression integral in response to heart-rate-limited exercise had 3 times the rate of CAD death of those with a normal test response. Contrary to the result that had been predicted for the subgroup with a normal response, there was no SI-UC difference in CAD mortality. However, in the subgroup with an abnormal response, the CAD mortality rate was 57% lower in SI than UC participants.

26 **Relation of Antianginal Efficacy of Nifedipine to Degree of Coronary Arterial Narrowing and to Presence of Coronary Collateral Vessels**

WOLFGANG SCHULZ, STEFAN JOST, GISBERT KOBER, and MARTIN KALTENBACH

Patients who do not respond to nifedipine have been reported in many studies. A reflex tachycardia, cited as explanation, is often not present. To test if there is evidence for a "coronary steal" phenomenon in patients who do not respond to nifedipine treatment, 36 selected patients with coronary artery disease were separated into 2 groups: those in whom a coronary steal appeared possible (occlusions and collaterals, group B, C and D) and those in whom it was not possible (stenoses and no collaterals, group A). Patients underwent repetitive exercise tests after double-blinded crossover treatment with 20 mg of nifedipine, 20 mg of isosorbide dinitrate, the combination of both and placebo. After nifedipine, ST-segment depression and angina pectoris were reduced only in group A; after isosorbide dinitrate, ST-segment depression and angina pectoris were reduced in all groups. An inadequate increase in heart rate was not found among those who did not respond to nifedipine. It is concluded that steal-like mechanisms are responsible for the lack of response to nifedipine treatment.

33 **Coronary Hemodynamic and Metabolic Effects of Nifedipine in Patients with Coronary Artery Disease Treated with Beta-Blocking Drugs**

PETER SCHANZENBÄCHER, GERHARD GÖTTFERT, GERHART LIEBAU, and KURT KOCHSIEK

The coronary hemodynamic and metabolic effects of nifedipine were studied after propranolol-induced β-receptor blockade in 12 patients with coronary artery disease. Propranolol led to a decrease in heart rate, coronary blood flow and myocardial oxygen consumption and to an increase in coronary vascular resistance and the coronary arteriovenous oxygen difference. Subsequent administration of nifedipine resulted in a transient increase in coronary blood flow, a reduction in coronary vascular resistance and the coronary arteriovenous oxygen dif-

MJL 4-4972

Mead Johnson PHARMACEUTICAL DIVISIO

Klotrix®
(potassium chloride) CONTROLLED-RELEASE TABLETS, 10 mEq

DESCRIPTION KLOTRIX is a film-coated (not enteric-coated) tablet containing 750 mg potassium chloride (equivalent to 10 mEq) in a wax matrix. This formulation is intended to provide a controlled release of potassium from the matrix to minimize the likelihood of producing high localized concentrations of potassium within the gastrointestinal tract.

INDICATIONS—BECAUSE OF REPORTS OF INTESTINAL AND GASTRIC ULCERATION AND BLEEDING WITH SLOW-RELEASE POTASSIUM CHLORIDE PREPARATIONS, THESE DRUGS SHOULD BE RESERVED FOR THOSE PATIENTS WHO CANNOT TOLERATE OR REFUSE TO TAKE LIQUID OR EFFERVESCENT POTASSIUM PREPARATIONS OR FOR PATIENTS IN WHOM THERE IS A PROBLEM OF COMPLIANCE WITH THESE PREPARATIONS.

1. For therapeutic use in patients with hypokalemia with or without metabolic alkalosis; in digitalis intoxication and in patients with hypokalemic familial periodic paralysis.
2. For prevention of potassium depletion when the dietary intake of potassium is inadequate in the following conditions: Patients receiving digitalis and diuretics for congestive heart failure; hepatic cirrhosis with ascites; states of aldosterone excess with normal renal function; potassium-losing nephropathy, and certain diarrheal states.
3. The use of potassium salts in patients receiving diuretics for uncomplicated essential hypertension is often unnecessary when such patients have a normal dietary pattern. Serum potassium should be checked periodically, however, and, if hypokalemia occurs, dietary supplementation with potassium-containing foods may be adequate to control milder cases. In more severe cases supplementation with potassium salts may be indicated.

CONTRAINDICATIONS In patients with hyperkalemia, since a further increase in serum potassium concentration in such patients can produce cardiac arrest. Hyperkalemia may complicate any of the following conditions: chronic renal failure, systemic acidosis such as diabetic acidosis, acute dehydration, extensive tissue breakdown as in severe burns, adrenal insufficiency, or the administration of a potassium-sparing diuretic (*eg,* spironolactone, triamterene).

Wax-matrix potassium chloride preparations have produced esophageal ulceration in certain cardiac patients with esophageal compression due to enlarged left atrium.

All solid dosage forms of potassium supplements are contraindicated in any patient in whom there is cause for arrest or delay in tablet passage through the G.I. tract. In these instances, potassium supplementation should be with a liquid preparation.

WARNINGS Hyperkalemia: In patients with impaired mechanisms for excreting potassium, administration of potassium salts can produce hyperkalemia and cardiac arrest. This occurs most commonly in patients given potassium intravenously but may also occur when given orally. Potentially fatal hyperkalemia can develop rapidly and be asymptomatic. Use of potassium salts in patients with chronic renal disease, or any other condition which impairs potassium excretion requires particularly careful monitoring of the serum potassium concentration and appropriate dosage adjustment.

Interaction with potassium-sparing diuretics: Hypokalemia should not be treated by the concomitant administration of potassium salts and a potassium-sparing diuretic (*eg,* spironolactone or triamterene), since the simultaneous administration of these agents can produce severe hyperkalemia.

Gastrointestinal lesions: Potassium chloride tablets have produced stenotic and/or ulcerative lesions of the small bowel and deaths. These lesions are caused by a high localized concentration of potassium ion in the region of a rapidly dissolving tablet, which injures the bowel wall and thereby produces obstruction, hemorrhage, or perforation. KLOTRIX is a wax-matrix tablet formulated to provide a controlled rate of release of potassium chloride and thus to minimize the possibility of a high local concentration of potassium ion near the bowel wall. While the reported frequency of small-bowel lesions is much less with wax-matrix tablets (less than one per 100,000 patient-years) than with enteric-coated potassium chloride tablets (40-50 per 100,000 patient-years) cases associated with wax-matrix tablets have been reported both in foreign countries and in the United States. In addition, perhaps because the wax-matrix preparations are not enteric-coated and release potassium in the stomach, there have been reports of upper gastrointestinal bleeding associated with these products. The total number of gastrointestinal lesions remains less than one per 100,000 patient-years. KLOTRIX should be discontinued immediately and the possibility of bowel obstruction or perforation considered if severe vomiting, abdominal pain, distention, or gastrointestinal bleeding occurs.

Metabolic acidosis: Hypokalemia in patients with metabolic *acidosis* should be treated with an alkalinizing potassium salt such as potassium bicarbonate, potassium citrate, or potassium acetate.

PRECAUTIONS Potassium depletion is ordinarily diagnosed by demonstrating hypokalemia in a patient with a clinical history suggesting some cause for potassium depletion. In interpreting the serum potassium level, the physician should bear in mind that acute alkalosis *per se* can produce hypokalemia in the absence of a deficit in total body potassium, while acute acidosis *per se* can increase the serum potassium concentration into the normal range even in the presence of a reduced total body potassium. Treatment of potassium depletion particularly in presence of cardiac disease, renal disease, or acidosis, requires careful attention to acid-base balance and appropriate monitoring of serum electrolytes, electrocardiogram and clinical status of patient.

ADVERSE REACTIONS Most common to oral potassium salts: nausea, vomiting, abdominal discomfort, and diarrhea. These symptoms are due to irritation of the gastrointestinal tract and are best managed by diluting the preparation further, taking the dose with meals, or reducing the dose. One of the most severe adverse effects is hyperkalemia (see Contraindications and Warnings). There also have been reports of upper and lower gastrointestinal conditions including obstruction, bleeding, ulceration and perforation (see Contraindications and Warnings); other factors known to be associated with such conditions were present in many of these patients. Skin rash has been reported rarely.

DOSAGE AND ADMINISTRATION The usual dietary intake of potassium by the average adult is 40 to 80 mEq per day. Potassium depletion sufficient to cause hypokalemia usually requires the loss of 200 or more mEq of potassium from the total body store. Dosage must be adjusted to the individual needs of each patient but is typically in the range of 20 mEq per day for the prevention of hypokalemia to 40-100 mEq per day or more for the treatment of potassium depletion.

Note: KLOTRIX® slow-release tablets must be swallowed whole and never crushed or chewed. Following release of the potassium chloride, the expended wax matrix, which is not absorbed, may be observed in the stool.

HOW SUPPLIED Bottles of 100, 1000, and Unit Dose cartons of 100.

Obsolescence Proofing

Patient Monitoring

Marquette Electronics new ICU, CCU, O.R. and Telemetry Monitoring Systems have many innovative features. However, one feature is much more important than all the rest when considering current financial constraints and that is a design that guards against obsolescence.

By providing plug-in input modules and performing all functions with software (not hardware) we greatly reduce the danger of your investment becoming obsolete.

You see, when new developments come along, we offer revised plug-in modules and/or 'chips' with new software so almost any up-dating can be made right in your hospital — and at a minimal cost.

So before you invest in a critical care monitoring system of any kind, check with Marquette Electronics. In the long run, you'll be glad you did.

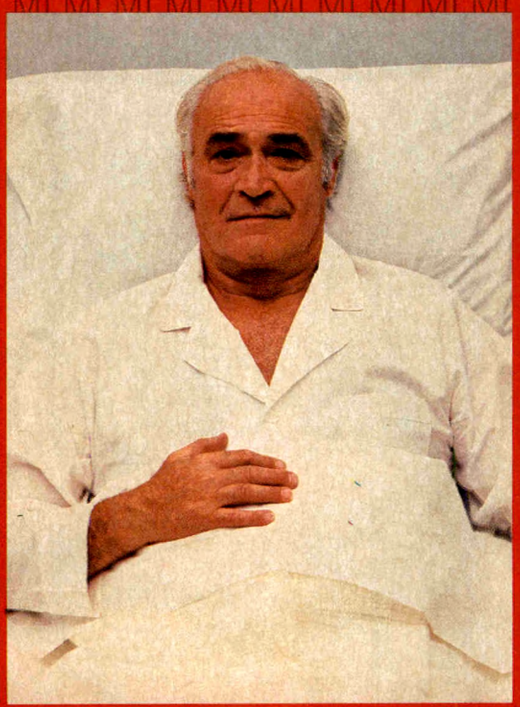
BEFORE THE NEXT MI...



CARDIOPROTECTIVE JUST 10 MG B.I.D. TABLETS

BLOCADREN®

(TIMOLOL MALEATE | MSD)

NOW!

7 to 28 days after this MI

To reduce the risk of cardiovascular mortality and reinfarction in many stabilized patients who have survived the acute phase of an MI

Results from a major clinical study[1]

Reduces sudden death by 44.6% (death within 24 hours)

Reduces instantaneous death by 71.4% (death occurring within a few seconds)

Reduces overall mortality by 39.4%

Reduces reinfarction by 28.4%

It is recommended that treatment should be initiated within 1 to 4 weeks after infarction. Data are not available as to whether benefit would ensue if BLOCADREN is initiated later.

1. The Norwegian Multicenter Study Group: Timolol-induced reduction in mortality and reinfarction in patients surviving acute myocardial infarction, N. Engl. J. Med. *304(14)*:801-807, April 2, 1981.

BLOCADREN is contraindicated in patients with bronchial asthma, a history of bronchial asthma, or severe chronic obstructive pulmonary disease (see below); sinus bradycardia; second- and third-degree atrioventricular block; overt cardiac failure (see below); cardiogenic shock; and hypersensitivity to this product.

Although beta blockers should be avoided in overt congestive heart failure, they can be used, if necessary, with caution in patients with a history of failure who are well compensated. In patients without a history of cardiac failure, continued depression of the myocardium with beta-blocking agents over a period of time can, in some cases, lead to cardiac failure.

Exacerbation of Ischemic Heart Disease following Abrupt Withdrawal—Hypersensitivity to catecholamines has been observed in patients withdrawn from beta-blocker therapy; exacerbation of angina and, in some cases, myocardial infarction have occurred after abrupt discontinuation of such therapy. When discontinuing chronically administered timolol maleate, particularly in patients with ischemic heart disease, the dosage should be gradually reduced over a period of one to two weeks, and the patient should be carefully monitored. If angina markedly worsens or acute coronary insufficiency develops, timolol maleate administration should be reinstituted promptly, at least temporarily, and other measures appropriate for the management of unstable angina should be taken. Patients should be warned against interruption or discontinuation of therapy without the physician's advice. Because coronary artery disease is common and may be unrecognized, it may be prudent not to discontinue timolol maleate therapy abruptly even in patients treated only for hypertension.

In patients with nonallergic bronchospasm or with a history of nonallergic bronchospasm (e.g., chronic bronchitis, emphysema), BLOCADREN should be administered with caution.

BLOCADREN®
(TIMOLOL MALEATE | MSD)

CONTRAINDICATIONS:

BLOCADREN is contraindicated in patients with bronchial asthma, a history of bronchial asthma, or severe chronic obstructive pulmonary disease (see WARNINGS); sinus bradycardia; second- and third-degree atrioventricular block; overt cardiac failure (see WARNINGS); cardiogenic shock; hypersensitivity to this product.

WARNINGS:

Cardiac Failure: Sympathetic stimulation may be essential for support of the circulation in individuals with diminished myocardial contractility, and its inhibition by beta-adrenergic receptor blockade may precipitate more severe failure. Although beta blockers should be avoided in overt congestive heart failure, they can be used, if necessary, with caution in patients with a history of failure who are well compensated, usually with digitalis and diuretics. Both digitalis and timolol maleate slow AV conduction. If cardiac failure persists, therapy with BLOCADREN should be withdrawn.

In Patients without a History of Cardiac Failure: Continued depression of the myocardium with beta-blocking agents over a period of time can, in some cases, lead to cardiac failure. At the first sign or symptom of cardiac failure, patients receiving BLOCADREN should be digitalized and/or be given a diuretic, and the response observed closely. If cardiac failure continues despite adequate digitalization and diuretic therapy, BLOCADREN should be withdrawn.

Exacerbation of Ischemic Heart Disease following Abrupt Withdrawal – Hypersensitivity to catecholamines has been observed in patients withdrawn from beta-blocker therapy; exacerbation of angina and, in some cases, myocardial infarction have occurred after *abrupt* discontinuation of such therapy. When discontinuing chronically administered timolol maleate, particularly in patients with ischemic heart disease, the dosage should be gradually reduced over a period of one to two weeks and the patient should be carefully monitored. If angina markedly worsens or acute coronary insufficiency develops, timolol maleate administration should be reinstituted promptly, at least temporarily, and other measures appropriate for the management of unstable angina should be taken. Patients should be warned against interruption or discontinuation of therapy without the physician's advice. Because coronary artery disease is common and may be unrecognized, it may be prudent not to discontinue timolol maleate therapy abruptly even in patients treated only for hypertension.

Nonallergic Bronchospasm: In patients with nonallergic bronchospasm or with a history of nonallergic bronchospasm (e.g., chronic bronchitis, emphysema), BLOCADREN should be administered with caution since it may block bronchodilation produced by endogenous and exogenous catecholamine stimulation of $beta_2$ receptors.

Major Surgery: The necessity or desirability of withdrawal of beta-blocking therapy prior to major surgery is controversial. Beta-adrenergic receptor blockade impairs the ability of the heart to respond to beta-adrenergically mediated reflex stimuli. This may augment the risk of general anesthesia in surgical procedures. Some patients receiving beta-adrenergic receptor blocking agents have been subject to protracted severe hypotension during anesthesia. Difficulty in restarting and maintaining the heartbeat has also been reported. For these reasons, in patients undergoing elective surgery, some authorities recommend gradual withdrawal of beta-adrenergic receptor blocking agents.

If necessary during surgery, the effects of beta-adrenergic blocking agents may be reversed by sufficient doses of such agonists as isoproterenol, dopamine, dobutamine, or levarterenol (see OVERDOSAGE).

Diabetes Mellitus: BLOCADREN should be administered with caution in patients subject to spontaneous hypoglycemia or to diabetic patients (especially those with labile diabetes) who are receiving insulin or oral hypoglycemic agents. Beta-adrenergic receptor blocking agents may mask the signs and symptoms of acute hypoglycemia.

Thyrotoxicosis: Beta-adrenergic blockade may mask certain clinical signs (e.g., tachycardia) of hyperthyroidism. Patients suspected of developing thyrotoxicosis should be managed carefully to avoid abrupt withdrawal of beta blockade which might precipitate a thyroid storm.

PRECAUTIONS:

General: Impaired Hepatic or Renal Function: Since BLOCADREN is partially metabolized in the liver and excreted mainly by the kidneys, dosage reductions may be necessary when hepatic and/or renal insufficiency is present.

Dosing in the Presence of Marked Renal Failure: Marked hypotensive responses have been seen in patients with marked renal impairment undergoing dialysis after 20-mg doses. Dosing in such patients should therefore be especially cautious.

Muscle Weakness: Beta-adrenergic blockade has been reported to potentiate muscle weakness consistent with certain myasthenic symptoms (e.g., diplopia, ptosis, and generalized weakness). Timolol has been reported rarely to increase muscle weakness in some patients with myasthenic symptoms.

Drug Interactions: Close observation of the patient is recommended when BLOCADREN® (Timolol Maleate, MSD) is administered to patients receiving catecholamine-depleting drugs such as reserpine, because of possible additive effects and the production of hypotension and/or marked bradycardia which may produce vertigo, syncope, or postural hypotension.

Blunting of the antihypertensive effect of beta-adrenoceptor blocking agents by nonsteroidal anti-inflammatory drugs has been reported. When using these agents concomitantly, patients should be observed carefully to confirm that the desired therapeutic effect has been obtained.

Carcinogenesis, Mutagenesis, Impairment of Fertility: In a two-year study of timolol maleate in rats, there was a statistically significant ($p \leq 0.05$) increase in the incidence of adrenal pheochromocytomas in male rats administered 300 times the maximum recommended human dose (1 mg/kg/day). Similar differences were not observed in rats administered doses equivalent to 25 or 100 times the maximum recommended human dose. In a lifetime study in mice, there were statistically significant ($p \leq 0.05$) increases in the incidence of benign and malignant pulmonary tumors and benign uterine polyps in female mice at 500 mg/kg/day, but not at 5 or 50 mg/kg/day. There was also a significant increase in mammary adenocarcinomas at the 500-mg/kg/day dose. This was associated with elevations in serum prolactin which occurred in female mice administered timolol at 500 mg/kg, but not at doses of 5 or 50 mg/kg/day. An increased incidence of mammary adenocarcinomas in rodents has been associated with administration of several other therapeutic agents which elevate serum prolactin, but no correlation between serum prolactin levels and mammary tumors has been established in man. Furthermore, in adult human female subjects who received oral dosages of up to 60 mg of timolol maleate, the maximum recommended human oral dosage, there were no clinically meaningful changes in serum prolactin.

There was a statistically significant increase ($p \leq 0.05$) in the overall incidence of neoplasms in female mice at the 500-mg/kg/day dosage level.

Timolol maleate was devoid of mutagenic potential when evaluated *in vivo* (mouse) in the micronucleus test and cytogenetic assay (doses up to 800 mg/kg) and *in vitro* in a neoplastic cell transformation assay (up to 100 μg/ml). In Ames tests the highest concentrations of timolol employed, 5,000 or 10,000 μg/plate, were associated with statistically significant elevations ($p \leq 0.05$) of revertants observed with tester strain TA100 (in seven replicate assays), but not in the remaining three strains. In the assays with tester strain TA100, no consistent dose response relationship was observed, nor did the ratio of test to control revertants reach 2. A ratio of 2 is usually considered the criterion for a positive Ames test.

Reproduction and fertility studies in rats showed no adverse effect on male or female fertility at doses up to 150 times the maximum recommended human dose.

Pregnancy – Category C: Should be used during pregnancy only if the potential benefit justifies the potential risk to the fetus.

Nursing Mothers: Because of the potential for serious adverse reactions from timolol in nursing infants, a decision should be made whether to discontinue nursing or to discontinue the drug, taking into account the importance of the drug to the mother.

Pediatric Use: Safety and effectiveness in children have not been established.

ADVERSE REACTIONS:

BLOCADREN is usually well tolerated in properly selected patients. Most adverse effects have been mild and transient.

In a multicenter (12-week) clinical trial comparing timolol maleate and placebo, the following adverse reactions were reported spontaneously and considered to be causally related to timolol maleate:

	Timolol Maleate (n=176) %	Placebo (n=168) %
BODY AS A WHOLE		
fatigue/tiredness	3.4	0.6
headache	1.7	1.8
chest pain	0.6	0
asthenia	0.6	0
CARDIOVASCULAR		
bradycardia	9.1	0
arrhythmia	1.1	0.6
syncope	0.6	0
edema	0.6	1.2
DIGESTIVE		
dyspepsia	0.6	0.6
nausea	0.6	0
SKIN		
pruritus	1.1	0
NERVOUS SYSTEM		
dizziness	2.3	1.2
vertigo	0.6	0
paresthesia	0.6	0
PSYCHIATRIC		
decreased libido	0.6	0
RESPIRATORY		
dyspnea	1.7	0.6
bronchial spasm	0.6	0
rales	0.6	0
SPECIAL SENSES		
eye irritation	1.1	0.6
tinnitus	0.6	0

These data are representative of the incidence of adverse effects that may be observed in a properly selected hypertensive patient population, e.g., a group excluding patients with bronchospastic disease, congestive heart failure, or other contraindications to beta-blocker therapy. These adverse reactions can also occur in patients with coronary artery disease.

In a different population, the coronary artery disease population, studied in the Norwegian multicenter trial (see CLINICAL PHARMACOLOGY), the frequency of the principal adverse reactions and the frequency with which these resulted in discontinuation of therapy in the timolol and placebo groups were:

	Adverse Reaction†		Withdrawal‡	
	Timolol (n=945) %	Placebo (n=939) %	Timolol (n=945) %	Placebo (n=939) %
Asthenia or Fatigue	5	1	<1	<1
Heart Rate <40 beats/minute	5	<1	4	<1
Cardiac Failure – Nonfatal	8	7	3	2
Hypotension	3	2	3	1
Pulmonary Edema – Nonfatal	2	<1	<1	<1
Claudication	3	3	1	<1

Nausea or Digestive Disorders	8	6	1	<1
Dizziness	6	4	1	0
Bronchial Obstruction	2	<1	1	<1

†When an adverse reaction recurred in a patient, it is listed only once.

‡Only principal reason for withdrawal in each patient is listed. These adverse reactions can also occur in patients treated for hypertension.

The following additional adverse effects have been reported in clinical experience with the drug: *Body as a Whole:* extremity pain, decreased exercise tolerance, weight loss; *Cardiovascular:* cardiac failure, cerebral vascular accident, worsening of angina pectoris, worsening of arterial insufficiency, Raynaud's phenomenon, palpitations, vasodilatation; *Digestive:* gastrointestinal pain, hepatomegaly, vomiting, diarrhea, dyspepsia; *Hematologic:* nonthrombocytopenic purpura; *Endocrine:* hyperglycemia, hypoglycemia; *Skin:* rash, skin irritation, increased pigmentation, sweating; *Musculoskeletal:* arthralgia; *Nervous System:* local weakness; *Psychiatric:* depression, nightmares, somnolence, insomnia, nervousness, diminished concentration, hallucinations; *Respiratory:* cough; *Special Senses:* visual disturbances, diplopia, ptosis, dry eyes; *Urogenital:* impotence, urination difficulties.

There have been reports of retroperitoneal fibrosis in patients receiving timolol maleate and in patients receiving other beta-adrenergic blocking agents. A causal relationship between this condition and therapy with beta-adrenergic blocking agents has not been established.

Potential Adverse Effects: In addition, a variety of adverse effects not observed in clinical trials with BLOCADREN® (Timolol Maleate, MSD), but reported with other beta-adrenergic blocking agents, should be considered potential adverse effects of BLOCADREN: *Nervous System:* reversible mental depression progressing to catatonia; an acute reversible syndrome characterized by disorientation for time and place, short-term memory loss, emotional lability, slightly clouded sensorium, and decreased performance on neuropsychometrics; *Cardiovascular:* intensification of AV block (see CONTRAINDICATIONS); *Digestive:* mesenteric arterial thrombosis, ischemic colitis; *Hematologic:* agranulocytosis, thrombocytopenic purpura; *Allergic:* erythematous rash, fever combined with aching and sore throat, laryngospasm and respiratory distress; *Miscellaneous:* reversible alopecia, Peyronie's disease. Multisystem syndrome reported with practolol.

Clinical Laboratory Test Findings: Slight increases in blood urea nitrogen, serum potassium, and serum uric acid, and slight decreases in hemoglobin and hematocrit occurred, but were not progressive or associated with clinical manifestations. 183 (DC7117616)

MSD MERCK SHARP & DOHME

ference and a sustained decrease in mean aortic pressure and myocardial oxygen consumption. Thus, the ability of nifedipine to dilate the coronary vasculature was effective in reversing the inappropriate vasoconstriction caused by propranolol, while maintaining an oxygen saving effect for the heart.

37 Value of Arm Exercise Testing in Detecting Coronary Artery Disease

GARY J. BALADY, DONALD A. WEINER, CAROLYN H. McCABE, and THOMAS J. RYAN

To determine the sensitivity of arm exercise in detecting coronary artery disease, 30 patients with a history of angina and angiographically proved CAD (≥70% stenosis in 1 or more vessels) performed both arm ergometry and treadmill testing. Ischemic ST-segment depression (>1 mm) or angina occurred more frequently with leg exercise than with arm exercise (86% vs 40%, respectively $p < 0.001$), although there was no significant difference in peak rate-pressure product achieved with either test. Peak oxygen consumption was greater during leg exercise than during arm exercise (18 vs 13 ml/kg/min, $p < 0.001$). For the patients with concordantly positive tests, the oxygen consumption at the onset of ischemia was significantly lower during arm testing than during leg testing (12 vs 17 ml/kg/min, $p < 0.001$). There was no significant difference in heart rate during either test at the onset of ischemia. Thus, arm exercise testing is less sensitive than leg exercise in detecting CAD, but is a reasonable alternative in patients who cannot perform lower extremity exercise.

40 Coronary Risk Factors and Their Pathway of Action Through Coronary Raised Lesions, Coronary Stenoses and Coronary Death. Multivariate Statistical Analysis of an Autopsy Series: The Oslo Study

INGAR HOLME, LARS A. SOLBERG, LISA WEISSFELD, ANDERS HELGELAND, INGVAR HJERMANN, PAUL LEREN, JACK P. STRONG, and O. DALE WILLIAMS

From 1972 to 1980, results of 204 consecutive autopsy cases from the Oslo Study cohort of 16,202 40- to 49-year-old men were obtained from whom information of risk factors as serum cholesterol, high-density lipoprotein cholesterol, triglycerides, systolic blood pressure, cigarette smoking, physical activity at work and at leisure, and social class was available. This report describes the strong relation found between coronary raised lesions, coronary stenoses, and death from coronary heart disease and risk factors such as serum cholesterol, high-density lipoprotein cholesterol and blood pressure. None of the other coronary risk factors appeared to be significantly related to stenosis when raised lesion was used as an independent variable.

48 Percutaneous Transluminal Coronary Angioplasty After Intracoronary Streptokinase in Evolving Acute Myocardial Infarction

SILVIO E. PAPAPIETRO, WILLIAM A. H. MacLEAN, ALFRED W. H. STANLEY, Jr., RANDALL G. HESS, NAN CORLEY, JOAQUIN G. ARCINIEGAS, and TERRY B. COOPER

Percutaneous transluminal coronary angioplasty (PTCA) was attempted in 18 patients with acute myocardial infarction after administration of intracoronary streptokinase. After thrombolytic therapy, 11 patients had a severe residual stenosis and 7 patients a persistent total occlusion of the infarct-related artery. PTCA was successful in 13 of 18 patients (72%): in 9 of 11 with stenoses and in 4 of 7 with total occlusions. PTCA reduced the severity of the coronary diameter narrowing from 91 ± 2% to 27 ± 7% ($p < 0.001$) and the transstenotic pressure gradient from 38 ± 5 to 6 ± 2 mm Hg ($p < 0.01$). One patient in shock died during urgent coronary surgery after unsuccessful PTCA. One patient had anterolateral reinfarction with reocclusion of the left anterior descending artery 5 days after PTCA. Twelve patients had an uneventful hospital course, and cardiac catheterization before hospital discharge (8 to 17 days) revealed reocclusion of the infarct-related coronary artery in 3 and persistent patency of the artery in 9. Persistent patency of the infarct-related artery was associated with preservation of left ventricular end-diastolic volume (initial 86 ± 6 ml/m^2; follow-up 91 ± 6 ml/m^2), and improvement in left ventricular ejection fraction in some patients.

54 Positive Exercise Thallium-201 Test Responses in Patients with Less Than 50% Maximal Coronary Stenosis: Angiographic and Clinical Predictors

KENNETH A. BROWN, MARY OSBAKKEN, CHARLES A. BOUCHER, H. WILLIAM STRAUSS, GERALD M. POHOST, and ROBERT D. OKADA

The incidence and causes of abnormal thallium-201 myocardial perfusion studies in patients with maximal angiographic coronary stenosis of less than 50% were examined in 100 patients. Maximal coronary stenosis ranged from 0 to 40%. Logistic regression analysis was performed using clinical, exercise and angiographic data. Significant predictors of a positive stress thallium-201 test were: percent maximal coronary stenosis ($p < 0.0005$), propranolol use ($p < 0.01$), interaction of propranolol use and percent maximal stenosis ($p < 0.01$), and stress-induced chest pain ($p = 0.05$). Positive thallium tests were more common in patients with maximal stenosis of 21 to 40% compared to maximal stenosis of 0 to 20% and were especially common in patients with 21 to 40% stenoses who reached 85% maximal predicted heart rate. Patients taking propranolol more frequently had positive thallium-201 tests than patients not taking propranolol. Individual perfusion defects corresponded well to the

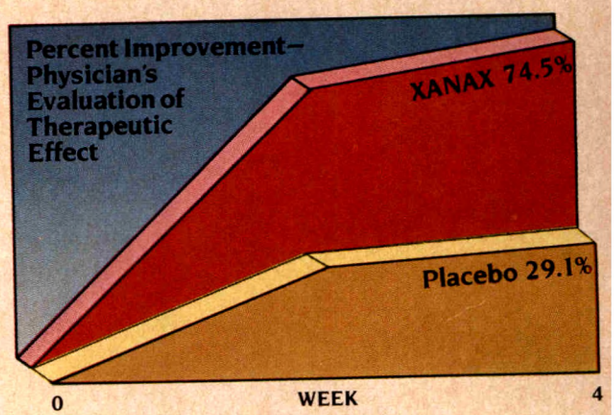
Xanax rapidly relieves anxiety...

In double-blind, four-week, clinical trials in 976 patients with moderate to severe anxiety, therapy with XANAX was compared with placebo.[1]

XANAX was significantly more effective ($p<0.001$) than placebo in relieving the anxiety, with over half of the patients showing marked to moderate improvement by the first evaluation period (one week).



...including cardiovascular symptoms of anxiety...

Most patients in the study had cardiovascular symptoms even though cardiovascular disease was ruled out. XANAX was shown to effectively relieve anxiety including the accompanying cardiovascular symptoms.

...and depressive symptoms of anxiety.

Over 70% of these patients experienced moderate to severe depressed mood. XANAX was shown to be significantly more effective ($p<0.014$) than placebo in improving depressed mood.

1. Cohn JB: Multicenter double-blind efficacy and safety study comparing alprazolam, diazepam and placebo in clinically anxious patients. *J Clin Psychiatry* 1981;42:347-351.

XANAX® Tablets
(alprazolam) ℞

CONTRAINDICATIONS
Patients with sensitivity to this drug or other benzodiazepines and in acute narrow angle glaucoma.

WARNINGS
Not of value in psychotic patients. Caution patients against hazardous occupations requiring complete mental alertness and about the simultaneous ingestion of alcohol and other CNS depressant drugs.

Benzodiazepines can cause fetal harm in pregnant women. Warn patients of the potential hazard to the fetus. Avoid during the first trimester.

PRECAUTIONS
General: The dosage of XANAX Tablets should be reduced or withdrawn gradually, since withdrawal seizures have been reported upon abrupt withdrawal. If XANAX is combined with other psychotropics or anticonvulsant drugs, consider drug potentiation. (See Drug Interaction section.) Exercise the usual precautions regarding size of the prescription for depressed or suicidal patients. In elderly and debilitated patients, use the lowest possible dosage. (See Dosage and Administration.) Observe the usual precautions in treating patients with impaired renal or hepatic function.

Information for Patients: Alert patients about: (a) consumption of alcohol and drugs, (b) possible fetal abnormalities, (c) operating machinery or driving, (d) not increasing dose of the drug due to risk of dependence, (e) not stopping the drug abruptly. *Laboratory Tests:* Not ordinarily required in otherwise healthy patients. *Drug Interactions:* Additive CNS depressant effects with other psychotropics, anticonvulsants, antihistamines, ethanol and other CNS depressants. Pharmacokinetic interactions with benzodiazepines have been reported. *Drug/Laboratory Test Interactions:* No consistent pattern for a specific drug or specific test. *Carcinogenesis, Mutagenesis, Impairment of Fertility:* No carcinogenic potential or impairment of fertility in rats. *Pregnancy:* See Warnings. *Nonteratogenic Effects:* The child born of a mother on benzodiazepines may be at some risk for withdrawal symptoms and neonatal flaccidity. *Labor and Delivery:* No established use. *Nursing Mothers:* Benzodiazepines are excreted in human milk. Women on XANAX should not nurse. *Pediatric Use:* Safety and effectiveness in children below the age of 18 have not been established.

ADVERSE REACTIONS
Side effects are generally observed at the beginning of therapy and usually disappear with continued medication. In the usual patient, the most frequent side effects are likely to be an extension of the pharmacological activity of XANAX, e.g., drowsiness or lightheadedness.

Central nervous system: Drowsiness, lightheadedness, depression, headache, confusion, insomnia, nervousness, syncope, dizziness, akathisia, and tiredness/sleepiness.

Gastrointestinal: Dry mouth, constipation, diarrhea, nausea/vomiting, and increased salivation.

Cardiovascular: Tachycardia/palpitations, and hypotension.

Sensory: Blurred vision.

Musculoskeletal: Rigidity and tremor.

Cutaneous: Dermatitis/allergy.

Other side effects: Nasal congestion, weight gain, and weight loss.

In addition, the following adverse events have been reported with the use of anxiolytic benzodiazepines: dystonia, irritability, concentration difficulties, anorexia, loss of coordination, fatigue, sedation, slurred speech, jaundice, musculoskeletal weakness, pruritus, diplopia, dysarthria, changes in libido, menstrual irregularities, incontinence and urinary retention.

Paradoxical reactions such as stimulation, agitation, increased muscle spasticity, sleep disturbances, and hallucinations may occur. Should these occur, discontinue the drug.

During prolonged treatment, periodic blood counts, urinalysis, and blood chemistry analysis are advisable. Minor EEG changes, of unknown significance, have been observed.

DRUG ABUSE AND DEPENDENCE
Physical and Psychological Dependence: Withdrawal symptoms have occurred following abrupt discontinuance of benzodiazepines. Withdrawal seizures have occurred upon rapid decrease or abrupt discontinuation of therapy. In all patients, dosage should be gradually tapered under close supervision. Patients with a history of seizures or epilepsy should not be abruptly withdrawn from XANAX. Addiction-prone individuals should be under careful surveillance. *Controlled Substance Class:* XANAX is a controlled substance and has been assigned to schedule IV.

DOSAGE AND ADMINISTRATION
The usual starting dose is 0.25 to 0.5 mg, t.i.d. Maximum total daily dose is 4 mg. In the elderly or debilitated, the usual starting dose is 0.25 mg, two or three times daily. Reduce dosage gradually when terminating therapy, by no more than one milligram every three days.

CAUTION: FEDERAL LAW PROHIBITS DISPENSING WITHOUT PRESCRIPTION.

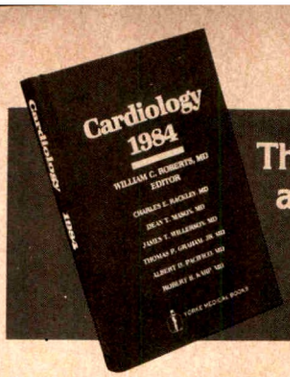
October 1984



The most important and best read annual publication on cardiology.

What is CARDIOLOGY 1984?

- ☐ The fourth in an annual series to be published in the summer each year — over 750 papers
- ☐ A review of the year's newest and most important developments in cardiology
- ☐ A **multidisciplinary** approach to clinical and applied research based on an exhaustive search of the year's literature
- ☐ A unique, cohesive summary of the state-of-the-art, **written,** not edited, by those making outstanding developments in the field
- ☐ A practical approach to a complicated and fast-moving subject designed to be read and used daily

Cardiology 1984 provides in a concise and readable format and style fundamental and new information essential to understanding the current thinking on managing cardiovascular disease. It coordinates what's new with well established data, arming the reader with a perspective on the field which is simply unavailable elsewhere. Its liberal use of illustrations and tables condenses valuable information into instantly understandable knowledge.

Who are the authors?

☐ William C. Roberts, MD Editor ☐ Charles E. Rackley, MD ☐ Dean T. Mason, MD ☐ James T. Willerson, MD ☐ Thomas P. Graham, Jr, MD ☐ Albert D. Pacifico, MD ☐ Robert B. Karp, MD

These seven leaders in their respective fields of cardiology have reviewed the year's literature in their own areas and have worked together coordinating their individual efforts into a cohesive whole.

presence of a 21 to 40% stenosis in the coronary artery that supplied that region. The high frequency of thallium-201 defects associated with 21 to 40% stenosis and an observed close correspondence of such defects with territory supplied by these stenoses suggests that such coronary lesions may have true hemodynamic impact. In addition, the high incidence of positive thallium-201 test results in patients taking propranolol suggests that an attempt be made to wean patients off β blockade before exercise thallium testing.

58 Collateral Circulation in Coronary Artery Disease

MacARTHUR A. ELAYDA, VIRENDRA S. MATHUR, ROBERT J. HALL, G. ALI MASSUMI, EFRAIN GARCIA, and CARLOS M. de CASTRO

Collateral circulation was assessed among patients with severe coronary artery disease. Two hundred two consecutive patients were studied. Of the 127 patients who had at least 1 major branch that was totally occluded, collateral circulation was seen angiographically in 125, whereas collateral circulation was seen in only 2 of the 75 patients without total occlusion; both had 99% (near-total) occlusion. Thus, collateral circulation cannot be seen angiographically unless there is total or near-total occlusion. Left ventricular wall motion analysis indicates that an akinetic area can exist despite good collateral flow and normal wall motion can be seen in area of occluded artery despite poor collateral flow to that segment.

61 Influence of Magnesium Ion on Human Ventricular Defibrillation After Aortocoronary Bypass Surgery

BERNICE R. HECKER, CAROL L. LAKE, IRVING L. KRON, ROBERT M. MENTZER, IVAN K. CROSBY, STANTON P. NOLAN, and RICHARD S. CRAMPTON

Although administration of magnesium ion (Mg^{++}) produces spontaneous ventricular defibrillation and decreases the incidence of arrhythmias in various clinical conditions, a beneficial effect of administration of Mg^{++} during cardiac surgery could not be demonstrated. Neither spontaneous ventricular defibrillation nor a decreased incidence of arrhythmias occurred. Administration of Mg^{++} before cardiopulmonary bypass increased the number of shocks and the level of energy required for direct ventricular defibrillation. Elevation of the concentration of plasma magnesium during cardiac surgery above 2.3 mg/dl, the midnormal range, cannot be recommended.

65 Remnant Saphenous Veins After Aortocoronary Bypass Grafting: Analysis of 3,394 Centimeters of Unused Vein from 402 Patients

BRUCE F. WALLER and WILLIAM C. ROBERTS

The status of saphenous veins intended for use as aortocoronary bypass grafts was determined from a histologic survey of 3,394 cm of unused veins excised from 402 patients who underwent bypass operations. Over 90% of 6,788 five-millimeter-long remnant segments had some degree of intimal fibrous thickening, including 16 (0.4%) segments from 10 patients that were narrowed 76 to 100% in cross-sectional area. Preexisting saphenous vein disease may account for some of the variability in intimal changes observed within the same bypass graft or among different grafts in the same patient.

ARRHYTHMIAS AND CONDUCTION DISTURBANCES

72 Chronic Lorcainide Therapy for Symptomatic Premature Ventricular Complexes: Efficacy, Pharmacokinetics and Evidence for Norlorcainide Antiarrhythmic Effect

R. HARDWIN MEAD, DEBORAH L. KEEFE, ROBERT E. KATES, and ROGER A. WINKLE

This study evaluates the long-term efficacy of lorcainide in suppressing chronic symptomatic ventricular premature beats, and examines the relation of arrhythmia suppression to plasma concentrations of lorcainide and norlorcainide, a metabolite that accumulates after repeated oral doses. Fourteen patients were treated with lorcainide, 200 to 400 mg/day; 12 achieved nearly complete suppression of arrhythmias within 1 year. Lorcainide and norlorcainide plasma concentrations remained stable after the first week of therapy. Antiarrhythmic activity persisted throughout the year. On drug withdrawal after 1 year, the norlorcainide washout half-life was more than twice that of lorcainide, and the return of arrhythmias occurred after the lorcainide plasma concentration had fallen to subtherapeutic levels, suggesting an antiarrhythmic effect of norlorcainide. Therapy was well tolerated in the majority of patients.

79 Flecainide: Long-Term Treatment Using a Reduced Dosing Schedule

DAVID FLOWERS, DEBORAH O'GALLAGHER, VILMA TORRES, DENNIS MIURA, and JOHN C. SOMBERG

Flecainide is a new antiarrhythmic agent that was initially prescribed at 200 mg twice daily, but after reports of early toxicity, the dose was reduced to 100 mg twice daily. The efficacy of flecainide at the reduced dosage regimen was studied in 40 patients. Programmed electrical stimulation induced sustained ventricular tachycardia in

SLOW-K® potassium chloride **slow-release tablets**

Brief Summary of Prescribing Information

DESCRIPTION

Slow-K is a sugar-coated (not enteric-coated) tablet containing 600 mg potassium chloride (equivalent to 8 mEq) in a wax matrix. This formulation is intended to provide a controlled release of potassium from the matrix to minimize the likelihood of producing high localized concentrations of potassium within the gastrointestinal tract.

INDICATIONS

BECAUSE OF REPORTS OF INTESTINAL AND GASTRIC ULCERATION AND BLEEDING WITH SLOW-RELEASE POTASSIUM CHLORIDE PREPARATIONS, THESE DRUGS SHOULD BE RESERVED FOR THOSE PATIENTS WHO CANNOT TOLERATE OR REFUSE TO TAKE LIQUID OR EFFERVESCENT POTASSIUM PREPARATIONS OR FOR PATIENTS IN WHOM THERE IS A PROBLEM OF COMPLIANCE WITH THESE PREPARATIONS.

1. For therapeutic use in patients with hypokalemia with or without metabolic alkalosis; in digitalis intoxication and in patients with hypokalemic familial periodic paralysis.
2. For prevention of potassium depletion when the dietary intake of potassium is inadequate in the following conditions: Patients receiving digitalis and diuretics for congestive heart failure; hepatic cirrhosis with ascites; states of aldosterone excess with normal renal function; potassium-losing nephropathy, and certain diarrheal states.
3. The use of potassium salts in patients receiving diuretics for uncomplicated essential hypertension is often unnecessary when such patients have a normal dietary pattern. Serum potassium should be checked periodically, however, and, if hypokalemia occurs, dietary supplementation with potassium-containing foods may be adequate to control milder cases. In more severe cases supplementation with potassium salts may be indicated.

CONTRAINDICATIONS

Potassium supplements are contraindicated in patients with hyperkalemia since a further increase in serum potassium concentration in such patients can produce cardiac arrest. Hyperkalemia may complicate any of the following conditions: chronic renal failure; systemic acidosis such as diabetic acidosis; acute dehydration; extensive tissue breakdown as in severe burns; adrenal insufficiency; or the administration of a potassium-sparing diuretic (*eg*, spironolactone, triamterene).

Wax-matrix potassium chloride preparations have produced esophageal ulceration in certain cardiac patients with esophageal compression due to an enlarged left atrium.

All solid dosage forms of potassium supplements are contraindicated in any patient in whom there is cause for arrest or delay in tablet passage through the gastrointestinal tract. In these instances, potassium supplementation should be with a liquid preparation.

WARNINGS

Hyperkalemia: In patients with impaired mechanisms for excreting potassium, the administration of potassium salts can produce hyperkalemia and cardiac arrest. This occurs most commonly in patients given potassium by the intravenous route but may also occur in patients given potassium orally. Potentially fatal hyperkalemia can develop rapidly and be asymptomatic.

The use of potassium salts in patients with chronic renal disease, or any other condition which impairs potassium excretion, requires particularly careful monitoring of the serum potassium concentration and appropriate dosage adjustment.

Interaction with Potassium-Sparing Diuretics: Hypokalemia should not be treated by the concomitant administration of potassium salts and a potassium-sparing diuretic (*eg*, spironolactone or triamterene), since the simultaneous administration of these agents can produce severe hyperkalemia.

Gastrointestinal lesions: Potassium chloride tablets have produced stenotic and/or ulcerative lesions of the small bowel and deaths. These lesions are caused by a high localized concentration of potassium ion in the region of a rapidly dissolving tablet, which injures the bowel wall and thereby produces obstruction, hemorrhage, or perforation. Slow-K is a wax-matrix tablet formulated to provide a controlled rate of release of potassium chloride and thus to minimize the possibility of a high local concentration of potassium ion near the bowel wall. While the reported frequency of small-bowel lesions is much less with wax-matrix tablets (less than one per 100,000 patient-years) than with enteric-coated potassium chloride tablets (40-50 per 100,000 patient-years),cases associated with wax-matrix tablets have been reported both in foreign countries and in the United States. In addition, perhaps because the wax-matrix preparations are not enteric-coated and release potassium in the stomach, there have been reports of upper gastrointestinal bleeding associated with these products. The total number of gastrointestinal lesions remains approximately one per 100,000 patient-years. Slow-K should be discontinued immediately and the possibility of bowel obstruction or perforation considered if severe vomiting, abdominal pain, distention, or gastrointestinal bleeding occurs.

Metabolic acidosis: Hypokalemia in patients with metabolic *acidosis* should be treated with an alkalinizing potassium salt such as potassium bicarbonate, potassium citrate, or potassium acetate.

PRECAUTIONS

The diagnosis of potassium depletion is ordinarily made by demonstrating hypokalemia in a patient with a clinical history suggesting some cause for potassium depletion. In interpreting the serum potassium level, the physician should bear in mind that acute alkalosis *per se* can produce hypokalemia in the absence of a deficit in total body potassium, while acute acidosis *per se* can increase the serum potassium concentration into the normal range even in the presence of a reduced total body potassium. The treatment of potassium depletion, particularly in the presence of cardiac disease, renal disease, or acidosis, requires careful attention to acid-base balance and appropriate monitoring of serum electrolytes, the electrocardiogram, and the clinical status of the patient.

ADVERSE REACTIONS

The most common adverse reactions to oral potassium salts are nausea, vomiting, abdominal discomfort, and diarrhea. These symptoms are due to irritation of the gastrointestinal tract and are best managed by diluting the preparation further, taking the dose with meals, or reducing the dose.

One of the most severe adverse effects is hyperkalemia (see Contraindications, Warnings and Overdosage). There also have been reports of upper and lower gastrointestinal conditions including obstruction, bleeding, ulceration and perforation (see Contraindications and Warnings); other factors known to be associated with such conditions were present in many of these patients. Skin rash has been reported rarely.

DOSAGE AND ADMINISTRATION

The usual dietary intake of potassium by the average adult is 40 to 80 mEq per day. Potassium depletion sufficient to cause hypokalemia usually requires the loss of 200 or more mEq of potassium from the total body store. Dosage must be adjusted to the individual needs of each patient but is typically in the range of 20 mEq per day for the prevention of hypokalemia to 40-100 mEq per day or more for the treatment of potassium depletion.

Note: Slow-K slow-release tablets must be swallowed whole and never crushed or chewed.

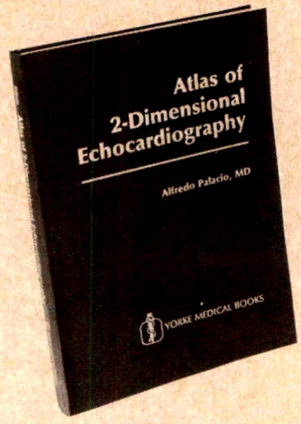
The First Practical Atlas of 2-D Echocardiography Ever Published



Atlas of 2-Dimensional Echocardiography

by Alfredo Palacio, MD
Director of National Institute of Cardiology, Guayaquil, Ecuador
Foreword by David H. Spodick, MD, DSc
Professor of Medicine, University of Massachusetts Medical School; Director, Division of Cardiology, St. Vincent Hospital, Worcester, Massachusetts

ISBN 0-914316-35-4, 198 pp, illus., large format 8¼ × 12, March '83, $69.00

2-dimensional echocardiography complemented by M-mode echocardiography has become one of the most common noninvasive diagnostic tools used by the cardiologist. With publication of the ATLAS OF 2-DIMENSIONAL ECHOCARDIOGRAPHY, neophyte and expert alike now have available to them the most truly usable didactic presentation of the subject ever published.

A true atlas, this book provides in a **large 8¼ × 12 format 251 black and white half tones, 152 line drawings and 6 charts** which illustrate in exacting detail how to perform and interpret 2-dimensional echocardiograms on patients with existing and/or suspected heart disease. The lucid accompanying text leads the reader step-by-step through the entire process, leaving little to the imagination. It presents in the most simple, direct way possible the broadest range of normal and abnormal 2-dimensional echocardiograms. The descriptions and detailed illustrations in its technical sections will ensure the superior level of performance of echocardiographic techniques that is a sine qua non for good results.

WE MAKE THE LESS EXPENSIVE MODEL.

At Cardio-Pace Medical, we make one and only one model pacemaker, the Durapulse™. We sell it for as little as one-third the price of competitive units, without any sacrifice in quality.

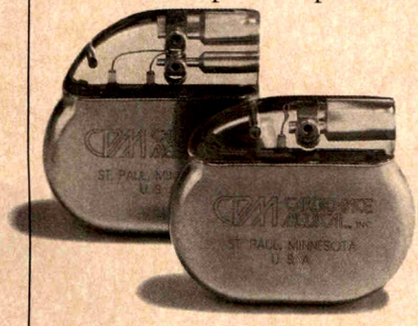
How are we able to sell a pacemaker for about a third of what our competitors charge?

The Durapulse™ is a single chamber pacemaker. It can be programmed to meet the needs of vast numbers of pacemaker users.

There are no bells. No whistles. No expensive and sometimes unnecessary options. No exorbitant markups.

We've priced this pacemaker to reflect the new realities of medical economics.

The DRG program is a symptom of an irreversible trend to lower medical costs, a trend based upon competitive factors, not "Sky's the Limit" prices.



We were the first to recognize that trend. That's why we're the leader in cost containment in the pacemaker industry.

At Cardio-Pace Medical we believe that making medical progress begins with making economic sense.

21 patients and nonsustained ventricular tachycardia in 19. Flecainide prevented ventricular tachycardia induction in 26 patients (65%). Twenty-one patients were discharged on flecainide therapy, 100 mg twice daily, and were followed up a mean of 11 months; all ventricular tachycardia events were abolished, with an 85% reduction in ectopy. Sixteen patients are alive and well, 1 patient died suddenly, 1 died from noncardiac causes and 1 had a breakthrough arrhythmia. Thus, flecainide therapy guided by programmed electrical stimulation is effective at a reduced dose.

84 Effect of Electrical Activation Site on Left Ventricular Performance in Ventricular Tachycardia Patients with Coronary Heart Disease

JOEL S. RAICHLEN, JONATHAN M. LINKS, and PHILIP R. REID

The effect of alterations in the site of ventricular activation was examined by endocardial pacing in 10 patients with coronary disease who were undergoing evaluation for recurrent ventricular arrhythmias. During right ventricular (RV) pacing sequences, radionuclide ventriculograms were acquired for calculation of left ventricular (LV) volumes. When compared to pacing from the RV outflow tract, RV apical pacing resulted in higher end-diastolic volume ($p = 0.020$), end-systolic volume ($p = 0.041$), stroke volume ($p = 0.046$), peak rate of LV ejection ($p = 0.034$), and peak rate normalized for differences in end-diastolic volume ($p = 0.047$). These higher volumes and ejection rates for RV apical vs RV outflow tract pacing occurred with different radionuclide patterns of emptying and an increase in LV/RV stroke count ratio ($p = 0.030$), suggesting the development of mitral regurgitation. These differences suggest that the anatomic site of origin for ectopic foci may be an important determinant of the hemodynamic consequences of ventricular tachycardia.

89 Intravenous and Oral Loading Versus Oral Loading Alone with Amiodarone for Chronic Refractory Ventricular Arrhythmias

NICHOLAS Z. KERIN, ROGER D. BLEVINS, HOWARD FRUMIN, KATHY FAITEL, and MELVYN RUBENFIRE

To determine whether combined intravenous (i.v.) and oral loading with amiodarone can shorten its onset of action, a comparative study was conducted. Twenty patients with refractory ventricular arrhythmias were referred for treatment with amiodarone. Ten patients (group A) were treated with oral loading (800 mg/day for 7 days, 600 mg/day for 3 days and then 200 to 400 mg/day), and 10 patients (group B) were treated first with i.v. loading (5 mg/kg) and then by the same regimen as group A. The time to optimal ventricular arrhythmia control was shorter for group B (20 ± 18 vs 105 ± 83 days, $p < 0.05$) and the cumulative amiodarone dose at the time of control was smaller for group B (10 ± 8 vs 48 ± 39 g, $p < 0.05$). Thus, initial loading with i.v. amiodarone can shorten the time to optimal ventricular arrhythmia control.

92 Intravenous Quinidine: Relations Among Concentration, Tachyarrhythmia Suppression and Electrophysiologic Actions with Inducible Sustained Ventricular Tachycardia

HENRY J. DUFF, D. GEORGE WYSE, DANTE MANYARI, and L. BRENT MITCHELL

Twenty-one patients with sustained inducible ventricular tachycardia received a quinidine sulfate infusion designed to produce pseudo-steady-state concentrations in the low and high therapeutic range, avoiding high peak concentrations. Mean concentrations produced approximated the target levels (12.6 ± 11 and then 18 ± 9 μM/liter); however, there was substantial interindividual variability. Transient hypotension occurred in 3 patients, none of whom had marked impairment of left ventricular ejection fraction. Inducible ventricular tachycardia was suppressed in 5 patients at low concentrations and in an additional 4 at high concentrations. Response to intravenous quinidine did not predict similar response during oral therapy. This discrepancy was at least in part a result of poor patient tolerance of high-dose oral quinidine.

98 Effect of the Calcium Antagonist Diltiazem on Atrioventricular Conduction in Chronic Atrial Fibrillation

KARL THEISEN, MATHIAS HAUFE, JOCHEN PETERS, FRANZ THEISEN, and HANS JAHRMÄRKER

Mean ventricular rates and RR-interval histograms were analyzed in 10 patients with stable atrial fibrillation after a single dose of diltiazem and during maintenance therapy. Diltiazem reduced the mean ventricular rate significantly in these patients. Two distinct types of changes were found in the RR-interval histograms, suggesting that in 50% of the patients the increase of the concealed conduction in the atrioventricular node was primarily the result of an increase in the atrial fibrillation rate; however, in the other 50% both prolonged atrioventricular refractory period and increased atrial fibrillation rate contributed to the increase of concealed conduction.

BALANCED CALCIUM CHANNEL BLOCKADE!

CARDIZEM®
(diltiazem HCl)

balances potent coronary vasodilation with a low incidence of side effects

Low incidence of side effects
CARDIZEM® (diltiazem HCl) produces an incidence of adverse reactions not greater than that reported with placebo therapy, thus contributing to the patient's sense of well-being.

*Cardizem is indicated in the treatment of angina pectoris due to coronary artery spasm and in the management of chronic stable angina (classic effort-associated angina) in patients who cannot tolerate therapy with beta-blockers and/or nitrates or who remain symptomatic despite adequate doses of these agents.

2. Pool PE, Seagren SC, Bonanno JA, et al: The treatment of exercise-inducible chronic stable angina with diltiazem: Effect on treadmill exercise. Chest 78 (July suppl):234-238, 1980.

Reduces angina attack frequency
42% to 46% decrease reported in multicenter study.[1]

Increases exercise tolerance*
In Bruce exercise test,[2] control patients averaged 8.0 minutes to onset of pain; Cardizem patients averaged 9.8 minutes ($P<.005$).

CARDIZEM®
(diltiazem HCl)

THE BALANCED CALCIUM CHANNEL BLOCKER

Please see full prescribing information on following page.

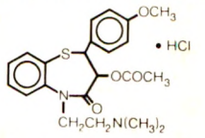
PROFESSIONAL USE INFORMATION

cardizem® (diltiazem HCl)

30 mg and 60 mg tablets

DESCRIPTION

CARDIZEM® (diltiazem hydrochloride) is a calcium ion influx inhibitor (slow channel blocker or calcium antagonist). Chemically, diltiazem hydrochloride is 1,5-Benzothiazepin-4(5H)one,3-(acetyloxy) -5-[2-(dimethylamino)ethyl]-2,3-dihydro-2-(4-methoxyphenyl)-, monohydrochloride,(+) -cis-. The chemical structure is:



Diltiazem hydrochloride is a white to off-white crystalline powder with a bitter taste. It is soluble in water, methanol, and chloroform. It has a molecular weight of 450.98. Each tablet of CARDIZEM contains either 30 mg or 60 mg diltiazem hydrochloride for oral administration.

CLINICAL PHARMACOLOGY

The therapeutic benefits achieved with CARDIZEM are believed to be related to its ability to inhibit the influx of calcium ions during membrane depolarization of cardiac and vascular smooth muscle.

Mechanisms of Action. Although precise mechanisms of its antianginal actions are still being delineated, CARDIZEM is believed to act in the following ways:

1. Angina Due to Coronary Artery Spasm: CARDIZEM has been shown to be a potent dilator of coronary arteries both epicardial and subendocardial. Spontaneous and ergonovine-induced coronary artery spasm are inhibited by CARDIZEM.
2. Exertional Angina: CARDIZEM has been shown to produce increases in exercise tolerance, probably due to its ability to reduce myocardial oxygen demand. This is accomplished via reductions in heart rate and systemic blood pressure at submaximal and maximal exercise work loads.

In animal models, diltiazem interferes with the slow inward (depolarizing) current in excitable tissue. It causes excitation-contraction uncoupling in various myocardial tissues without changes in the configuration of the action potential. Diltiazem produces relaxation of coronary vascular smooth muscle and dilation of both large and small coronary arteries at drug levels which cause little or no negative inotropic effect. The resultant increases in coronary blood flow (epicardial and subendocardial) occur in ischemic and nonischemic models and are accompanied by dose-dependent decreases in systemic blood pressure and decreases in peripheral resistance.

Hemodynamic and Electrophysiologic Effects. Like other calcium antagonists, diltiazem decreases sinoatrial and atrioventricular conduction in isolated tissues and has a negative inotropic effect in isolated preparations. In the intact animal, prolongation of the AH interval can be seen at higher doses.

In man, diltiazem prevents spontaneous and ergonovine-provoked coronary artery spasm. It causes a decrease in peripheral vascular resistance and a modest fall in blood pressure and, in exercise tolerance studies in patients with ischemic heart disease, reduces the heart rate-blood pressure product for any given work load. Studies to date, primarily in patients with good ventricular function, have not revealed evidence of a negative inotropic effect; cardiac output, ejection fraction, and left ventricular end diastolic pressure have not been affected. There are as yet few data on the interaction of diltiazem and beta-blockers. Resting heart rate is usually unchanged or slightly reduced by diltiazem.

Intravenous diltiazem in doses of 20 mg prolongs AH conduction time and AV node functional and effective refractory periods approximately 20%. In a study involving single oral doses of 300 mg of CARDIZEM in six normal volunteers, the average maximum PR prolongation was 14% with no instances of greater than first-degree AV block. Diltiazem-associated prolongation of the AH interval is not more pronounced in patients with first-degree heart block. In patients with sick sinus syndrome, diltiazem significantly prolongs sinus cycle length (up to 50% in some cases).

Chronic oral administration of CARDIZEM in doses of up to 240 mg/day has resulted in small increases in PR interval, but has not usually produced abnormal prolongation. There were, however, three instances of second-degree AV block and one instance of third-degree AV block in a group of 959 chronically treated patients.

Pharmacokinetics and Metabolism. Diltiazem is absorbed from the tablet formulation to about 80% of a reference capsule and is subject to an extensive first-pass effect, giving an absolute bioavailability (compared to intravenous dosing) of about 40%. CARDIZEM undergoes extensive hepatic metabolism in which 2% to 4% of the unchanged drug appears in the urine. In vitro binding studies show CARDIZEM is 70% to 80% bound to plasma proteins. Competitive ligand binding studies have also shown CARDIZEM binding is not altered by therapeutic concentrations of digoxin, hydrochlorothiazide, phenylbutazone, propranolol, salicylic acid, or warfarin. Single oral doses of 30 to 120 mg of CARDIZEM result in detectable plasma levels within 30 to 60 minutes and peak plasma levels two to three hours after drug administration. The plasma elimination half-life following single or multiple drug administration is approximately 3.5 hours. Desacetyl diltiazem is also present in the plasma at levels of 10% to 20% of the parent drug and is 25% to 50% as potent a coronary vasodilator as diltiazem. Therapeutic blood levels of CARDIZEM appear to be in the range of 50 to 200 ng/ml. There is a departure from dose-linearity when single doses above 60 mg are given; a 120-mg dose gave blood levels three times that of the 60-mg dose. There is no information about the effect of renal or hepatic impairment on excretion or metabolism of diltiazem.

INDICATIONS AND USAGE

1. **Angina Pectoris Due to Coronary Artery Spasm.** CARDIZEM is indicated in the treatment of angina pectoris due to coronary artery spasm. CARDIZEM has been shown effective in the treatment of spontaneous coronary artery spasm presenting as Prinzmetal's variant angina (resting angina with ST-segment elevation occurring during attacks).
2. **Chronic Stable Angina (Classic Effort-Associated Angina).** CARDIZEM is indicated in the management of chronic stable angina. CARDIZEM has been effective in controlled trials in reducing angina frequency and increasing exercise tolerance.

There are no controlled studies of the effectiveness of the concomitant use of diltiazem and beta-blockers or of the safety of this combination in patients with impaired ventricular function or conduction abnormalities.

CONTRAINDICATIONS

CARDIZEM is contraindicated in (1) patients with sick sinus syndrome except in the presence of a functioning ventricular pacemaker, (2) patients with second- or third-degree AV block except in the presence of a functioning ventricular pacemaker, and (3) patients with hypotension (less than 90 mm Hg systolic).

WARNINGS

1. **Cardiac Conduction.** CARDIZEM prolongs AV node refractory periods without significantly prolonging sinus node recovery time, except in patients with sick sinus syndrome. This effect may rarely result in abnormally slow heart rates (particularly in patients with sick sinus syndrome) or second- or third-degree AV block (six of 1243 patients for 0.48%). Concomitant use of diltiazem with beta-blockers or digitalis may result in additive effects on cardiac conduction. A patient with Prinzmetal's angina developed periods of asystole (2 to 5 seconds) after a single dose of 60 mg of diltiazem.
2. **Congestive Heart Failure.** Although diltiazem has a negative inotropic effect in isolated animal tissue preparations, hemodynamic studies in humans with normal ventricular function have not shown a reduction in cardiac index nor consistent negative effects on contractility (dp/dt). Experience with the use of CARDIZEM alone or in combination with beta-blockers in patients with impaired ventricular function is very limited. Caution should be exercised when using the drug in such patients.
3. **Hypotension.** Decreases in blood pressure associated with CARDIZEM therapy may occasionally result in symptomatic hypotension.
4. **Acute Hepatic Injury.** In rare instances, patients receiving CARDIZEM have exhibited reversible acute hepatic injury as evidenced by moderate to extreme elevations of liver enzymes. (See PRECAUTIONS and ADVERSE REACTIONS.)

PRECAUTIONS

General. CARDIZEM (diltiazem hydrochloride) is extensively metabolized by the liver and excreted by the kidneys and in bile. As with any new drug given over prolonged periods, laboratory parameters should be monitored at regular intervals. The drug should be used with caution in patients with impaired renal or hepatic function. In subacute and chronic dog and rat studies designed to produce toxicity, high doses of diltiazem were associated with hepatic damage. In special subacute hepatic studies, oral doses of 125 mg/kg and higher in rats were associated with histological changes in the liver which were reversible when the drug was discontinued. In dogs, doses of 20 mg/kg were also associated with hepatic changes; however, these changes were reversible with continued dosing.

Drug Interaction. Pharmacologic studies indicate that there may be additive effects in prolonging AV conduction when using beta-blockers or digitalis concomitantly with CARDIZEM. (See WARNINGS).

Controlled and uncontrolled domestic studies suggest that concomitant use of CARDIZEM and beta-blockers or digitalis is usually well tolerated. Available data are not sufficient, however, to predict the effects of concomitant treatment, particularly in patients with left ventricular dysfunction or cardiac conduction abnormalities. In healthy volunteers, diltiazem has been shown to increase serum digoxin levels up to 20%.

Carcinogenesis, Mutagenesis, Impairment of Fertility. A 24-month study in rats and a 21-month study in mice showed no evidence of carcinogenicity. There was also no mutagenic response in in vitro bacterial tests. No intrinsic effect on fertility was observed in rats.

Pregnancy. Category C. Reproduction studies have been conducted in mice, rats, and rabbits. Administration of doses ranging from five to ten times greater (on a mg/kg basis) than the daily recommended therapeutic dose has resulted in embryo and fetal lethality. These doses, in some studies, have been reported to cause skeletal abnormalities. In the perinatal/postnatal studies, there was some reduction in early individual pup weights and survival rates. There was an increased incidence of stillbirths at doses of 20 times the human dose or greater.

There are no well-controlled studies in pregnant women; therefore, use CARDIZEM in pregnant women only if the potential benefit justifies the potential risk to the fetus.

Nursing Mothers. It is not known whether this drug is excreted in human milk. Because many drugs are excreted in human milk, exercise caution when CARDIZEM is administered to a nursing woman if the drug's benefits are thought to outweigh its potential risks in this situation.

Pediatric Use. Safety and effectiveness in children have not been established.

ADVERSE REACTIONS

Serious adverse reactions have been rare in studies carried out to date, but it should be recognized that patients with impaired ventricular function and cardiac conduction abnormalities have usually been excluded.

In domestic placebo-controlled trials, the incidence of adverse reactions reported during CARDIZEM therapy was not greater than that reported during placebo therapy.

The following represent occurrences observed in clinical studies which can be at least reasonably associated with the pharmacology of calcium influx inhibition. In many cases, the relationship to CARDIZEM has not been established. The most common occurrences, as well as their frequency of presentation, are: edema (2.4%), headache (2.1%), nausea (1.9%), dizziness (1.5%), rash (1.3%), asthenia (1.2%), AV block (1.1%). In addition, the following events were reported infrequently (less than 1%) with the order of presentation corresponding to the relative frequency of occurrence.

Cardiovascular:	Flushing, arrhythmia, hypotension, bradycardia, palpitations, congestive heart failure, syncope.
Nervous System:	Paresthesia, nervousness, somnolence, tremor, insomnia, hallucinations, and amnesia.
Gastrointestinal:	Constipation, dyspepsia, diarrhea, vomiting, mild elevations of alkaline phosphatase, SGOT, SGPT, and LDH.
Dermatologic:	Pruritus, petechiae, urticaria, photosensitivity.
Other:	Polyuria, nocturia.

The following additional experiences have been noted:

A patient with Prinzmetal's angina experiencing episodes of vasospastic angina developed periods of transient asymptomatic asystole approximately five hours after receiving a single 60-mg dose of CARDIZEM.

The following postmarketing events have been reported infrequently in patients receiving CARDIZEM: erythema multiforme; leukopenia; and extreme elevations of alkaline phosphatase, SGOT, SGPT, LDH, and CPK. However, a definitive cause and effect between these events and CARDIZEM therapy is yet to be established.

OVERDOSAGE OR EXAGGERATED RESPONSE

Overdosage experience with oral diltiazem has been limited. Single oral doses of 300 mg of CARDIZEM have been well tolerated by healthy volunteers. In the event of overdosage or exaggerated response, appropriate supportive measures should be employed in addition to gastric lavage. The following measures may be considered:

Bradycardia	Administer atropine (0.60 to 1.0 mg). If there is no response to vagal blockade, administer isoproterenol cautiously.
High-Degree AV Block	Treat as for bradycardia above. Fixed high-degree AV block should be treated with cardiac pacing.
Cardiac Failure	Administer inotropic agents (isoproterenol, dopamine, or dobutamine) and diuretics.
Hypotension	Vasopressors (eg, dopamine or levarterenol bitartrate).

Actual treatment and dosage should depend on the severity of the clinical situation and the judgment and experience of the treating physician.

The oral LD_{50}'s in mice and rats range from 415 to 740 mg/kg and from 560 to 810 mg/kg, respectively. The intravenous LD_{50} s in these species were 60 and 38 mg/kg, respectively. The oral LD_{50} in dogs is considered to be in excess of 50 mg/kg, while lethality was seen in monkeys at 360 mg/kg. The toxic dose in man is not known, but blood levels in excess of 800 ng/ml have not been associated with toxicity.

DOSAGE AND ADMINISTRATION

Exertional Angina Pectoris Due to Atherosclerotic Coronary Artery Disease or Angina Pectoris at Rest Due to Coronary Artery Spasm. Dosage must be adjusted to each patient's needs. Starting with 30 mg four times daily, before meals and at bedtime, dosage should be increased gradually (given in divided doses three or four times daily) at one- to two-day intervals until optimum response is obtained. Although individual patients may respond to any dosage level, the average optimum dosage range appears to be 180 to 240 mg/day. There are no available data concerning dosage requirements in patients with impaired renal or hepatic function. If the drug must be used in such patients, titration should be carried out with particular caution.

Concomitant Use With Other Antianginal Agents:

1. **Sublingual NTG** may be taken as required to abort acute anginal attacks during CARDIZEM therapy.
2. **Prophylactic Nitrate Therapy**—CARDIZEM may be safely coadministered with short- and long-acting nitrates, but there have been no controlled studies to evaluate the antianginal effectiveness of this combination.
3. **Beta-blockers.** (See WARNINGS and PRECAUTIONS.)

HOW SUPPLIED

Cardizem 30-mg tablets are supplied in bottles of 100 (NDC 0088-1771-47) and in Unit Dose Identification Paks of 100 (NDC 0088-1771-49). Each green tablet is engraved with MARION on one side and 1771 engraved on the other. CARDIZEM 60-mg scored tablets are supplied in bottles of 100 (NDC 0088-1772-47) and in Unit Dose Identification Paks of 100 (NDC 0088-1772-49). Each yellow tablet is engraved with MARION on one side and 1772 on the other.

103 Electrocardiographic Diagnosis of Left Ventricular Hypertrophy in the Presence of Left Bundle Branch Block: An Echocardiographic Study

HENRYK KAFKA, GARY W. BURGGRAF, and JOHN A. MILLIKEN

M-mode echocardiography was used to estimate the left ventricular (LV) mass of 100 subjects with left bundle branch block. A calculated LV mass of at least 215 g and an LV mass index of at least 115 g/m^2 of body surface area were used as standards for increased LV mass (LV hypertrophy). Fifty-six percent had LV hypertrophy by mass alone and 71% by LV mass index. Four electrocardiographic parameters—R in aVL ≥ 11; QRS axis ≤ -40; $SV_1 + RV_5$ or $RV_6 \geq 40$; $SV_2 \geq 30$ and $SV_3 \geq 25$—used in cumulative fashion had a sensitivity of 73% and 75% and a specificity of 66% and 90%, respectively. The electrocardiographic criteria for LV hypertrophy in left bundle branch block are at least as reliable as in normal conduction.

SYSTEMIC HYPERTENSION

107 Serial Measurements of Systolic Time Intervals During Treatment with Hydrochlorothiazide Alone and Combined with Other Antihypertensive Agents

MARY C. KYLE and EDWARD D. FREIS

The major changes in systemic time intervals after administration of hydrochlorothiazide were a decrease in left ventricular ejection time corrected for heart rate and electromechanical systole and an increase in preejection period/left ventricular ejection time. Addition of either hydralazine, prazosin, oxprenolol or propranolol resulted a partial return of these values toward baseline. Although the return, indicating improvement in left ventricular performance, may have been due to the effects of the added drugs, it could also result from long-term hemodynamic changes associated with the diuretic drugs.

112 Enhanced 24-Hour Norepinephrine and Renin Secretion in Young Patients with Essential Hypertension: Relation with the Circadian Pattern of Arterial Blood Pressure

MICHAEL L. TUCK, NAFTALI STERN, and JAMES R. SOWERS

Arterial blood pressure (BP), plasma norepinephrine (NE) and plasma renin activity (PRA) levels were measured in 9 young normotensive subjects (mean age 24 ± 3 years) and 9 young patients with essential hypertension (mean age 29 ± 3 years) at 20-minute intervals over 24 hours. A distinct circadian rhythm was demonstrated for mean BP, NE and PRA in both groups. Circadian changes in mean BP correlated with NE in all subjects. Mean NE and PRA levels were higher in the hypertensive group throughout the 24-hour cycle, the differences being most accentuated during sleep. These findings provide evidence for increased basal sympathetic tone throughout the 24-hour cycle in young persons with essential hypertension.

116 Role of Prostaglandins in the Renal Handling of a Salt Load in Essential Hypertension

BRUNO TRIMARCO, ANTONIO DE SIMONE, ALBERTO CUOCOLO, BRUNO RICCIARDELLI, MASSIMO VOLPE, PAOLA PATRIGNANI, LUIGI SACCA, and MARIO CONDORELLI

Renal function and systemic hemodynamics were assessed in 10 hypertensive patients and in 10 age-matched normotensive subjects under control conditions and after a salt load either alone or combined with indomethacin or sulindac. Indomethacin was used as ubiquitous inhibitor of prostaglandin synthesis and sulindac was used to inhibit prostaglandin synthesis in all tissue except the kidney. The changes induced by the salt load were comparable in the 2 groups. However, after indomethacin, only hypertensive patients showed a significant reduction in the 24-hour sodium excretion; this reduction was significantly correlated with the changes in renal blood flow ($r = 0.803$, $p < 0.01$). After the addition of sulindac to the salt load, the differences in the 24-hour sodium excretion between the 2 groups vanished. Our data suggest that renal prostaglandins participate in renal disposal of a chronic salt load in hypertensive patients but not in normal persons.

CONGESTIVE HEART FAILURE

122 Immediate Converting-Enzyme Inhibition with Intravenous Enalapril in Chronic Congestive Heart Failure

SPENCER H. KUBO, ROBERT J. CODY, JOHN H. LARAGH, XAVIER E. PRIDA, STEVEN A. ATLAS, ZHUNG YUAN, and JEAN E. SEALEY

To test the hypothesis that intravenous enalapril is a useful pharmacologic probe of the renin angiotensin system, intravenous enalapril was administered to 9 patients with severe congestive heart failure. This produced abrupt and complete blockade of converting enzyme with peak effect at 30 minutes. Associated with the reduction of angiotensin II–mediated vasoconstriction, systemic vascular resistance decreased markedly and cardiac

start hypertensive

Minipress® for initial therapy
(prazosin HCl)

- Is effective when used alone
- Does not cause a significant incidence of sexual impotence, although it has been reported[1]
- Does not adversely affect blood lipids*[2]
- Does not lower heart rate, cardiac output or work capacity[3]
- Does not induce potassium wasting[4]
- The most common side effects with Minipress are: dizziness, headache, drowsiness, lack of energy, weakness, palpitations, nausea. With Minipress therapy there is a tendency for side effects to diminish with time. Syncope (sudden loss of consciousness) has been reported in about 0.15% of patients at an initial dose of 1 mg and in about 1% of patients at an initial dose of 2 mg

*Minipress is not indicated for the treatment of hyperlipidemia.

Minipress®
(prazosin HCl) Capsules 1 mg, 2 mg, 5 mg

for Initial Therapy in Hypertension

Please see Minipress brief summary on following page.

© 1983, Pfizer Inc.

Minipress®
(prazosin HCl) Capsules 1 mg, 2 mg, 5 mg

Brief Summary
MINIPRESS® (prazosin hydrochloride) Capsules ***For Oral Use***
INDICATIONS: MINIPRESS (prazosin hydrochloride) is indicated in the treatment of hypertension. As an antihypertensive drug, it is mild to moderate in activity. It can be used as the initial agent or it may be employed in a general treatment program in conjunction with a diuretic and/or other antihypertensive drugs as needed for proper patient response.
WARNINGS: Minipress may cause syncope with sudden loss of consciousness. In most cases this is believed to be due to an excessive postural hypotensive effect, although occasionally the syncopal episode has been preceded by a bout of severe tachycardia with heart rates of 120–160 beats per minute. Syncopal episodes have usually occurred within 30 to 90 minutes of the initial dose of the drug; occasionally they have been reported in association with rapid dosage increases or the introduction of another antihypertensive drug into the regimen of a patient taking high doses of MINIPRESS. The incidence of syncopal episodes is approximately 1% in patients given an initial dose of 2 mg or greater. Clinical trials conducted during the investigational phase of this drug suggest that syncopal episodes can be minimized by limiting the initial dose of the drug to 1 mg, by subsequently increasing the dosage slowly, and by introducing any additional antihypertensive drugs into the patient's regimen with caution. (See DOSAGE AND ADMINISTRATION.) Hypotension may develop in patients given MINIPRESS who are also receiving a beta-blocker such as propranolol.
If syncope occurs, the patient should be placed in the recumbent position and treated supportively as necessary. This adverse effect is self-limiting and in most cases does not recur after the initial period of therapy or during subsequent dose titration.
Patients should always be started on the 1 mg capsule of MINIPRESS. The 2 and 5 mg capsules are not indicated for initial therapy.
More common than loss of consciousness are the symptoms often associated with lowering of the blood pressure, namely, dizziness and lightheadedness. The patient should be cautioned about these possible adverse effects and advised what measures to take should they develop. The patient should also be cautioned to avoid situations where injury could result should syncope occur during the initiation of MINIPRESS therapy.
Usage in Pregnancy: Although no teratogenic effects were seen in animal testing, the safety of MINIPRESS in pregnancy has not been established. MINIPRESS is not recommended in pregnant women unless the potential benefit outweighs potential risk to mother and fetus.
Usage in Children: No clinical experience is available with the use of MINIPRESS in children.
ADVERSE REACTIONS: The most common reactions associated with MINIPRESS therapy are: dizziness 10.3%, headache 7.8%, drowsiness 7.6%, lack of energy 6.9%, weakness 6.5%, palpitations 5.3%, and nausea 4.9%. In most instances side effects have disappeared with continued therapy or have been tolerated with no decrease in dose of drug.
The following reactions have been associated with MINIPRESS some of them rarely. (In some instances exact causal relationships have not been established.)
Gastrointestinal: vomiting, diarrhea, constipation, abdominal discomfort and/or pain.
Cardiovascular: edema, dyspnea, syncope, tachycardia.
Central Nervous System: nervousness, vertigo, depression, paresthesia.
Dermatologic: rash, pruritus, alopecia, lichen planus.
Genitourinary: urinary frequency, incontinence, impotence, priapism.
EENT: blurred vision, reddened sclera, epistaxis, tinnitus, dry mouth, nasal congestion.
Other: diaphoresis.
Single reports of pigmentary mottling and serous retinopathy, and a few reports of cataract development or disappearance have been reported. In these instances the exact causal relationship has not been established because the baseline observations were frequently inadequate.
In more specific slit-lamp and funduscopic studies, which included adequate baseline examinations, no drug-related abnormal ophthalmological findings have been reported.
DOSAGE AND ADMINISTRATION: The dose of MINIPRESS should be adjusted according to the patient's individual blood pressure response. The following is a guide to its administration:
Initial Dose: 1 mg two or three times a day. (See WARNINGS.)
Maintenance Dose: Dosage may be slowly increased to a total daily dose of 20 mg given in divided doses. The therapeutic dosages most commonly employed have ranged from 6 mg to 15 mg daily given in divided doses. Doses higher than 20 mg usually do not increase efficacy; however a few patients may benefit from further increases up to a daily dose of 40 mg given in divided doses. After initial titration some patients can be maintained adequately on a twice daily dosage regimen.
Use With Other Drugs: When adding a diuretic or other antihypertensive agent, the dose of MINIPRESS should be reduced to 1 mg or 2 mg three times a day and retitration then carried out.
OVERDOSAGE: Accidental ingestion of at least 50 mg of MINIPRESS in a two year old child resulted in profound drowsiness and depressed reflexes. No decrease in blood pressure was noted. Recovery was uneventful.
Should overdosage lead to hypotension, support of the cardiovascular system is of first importance. Restoration of blood pressure and normalization of heart rate may be accomplished by keeping the patient in the supine position. If this measure is inadequate, shock should first be treated with volume expanders. If necessary, vasopressors should then be used. Renal function should be monitored and supported as needed. Laboratory data indicate MINIPRESS is not dialysable because it is protein bound.
TOXICOLOGY: Testicular changes, necrosis and atrophy have occurred at 25 mg/kg/day (60 times the usual maximum recommended dose of 20 mg per day in humans) in long term (one year or more) studies in rats and dogs. No testicular changes were seen in rats or dogs at the 10 mg/kg/day level (24 times the usual maximum recommended dose of 20 mg per day in humans). In view of the testicular changes observed in animals, 105 patients on long term MINIPRESS (prazosin hydrochloride) therapy were monitored for 17-ketosteroid excretion and no changes indicating a drug effect were observed. In addition, 27 males on MINIPRESS (prazosin hydrochloride) alone for up to 51 months did not demonstrate changes in sperm morphology suggestive of drug effect.
HOW SUPPLIED: MINIPRESS is available in 1 mg (white #431), 2 mg (pink and white #437) capsules in bottles of 250, 1000, and unit dose institutional packages of 100 (10 x 10's); and 5 mg (blue and white #438) capsules in bottles of 250, 500 and unit dose institutional packages of 100 (10 x 10's).

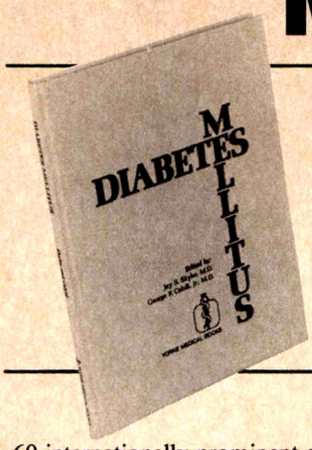
DIABETES MELLITUS



From the publishers of the American Journal of Medicine

Jay S. Skyler, M.D.,
University of Miami School of Medicine

George F. Cahill, Jr., M.D.,
Harvard Medical School and Howard Hughes Medical Institute

60 internationally prominent contributors provide in 26 papers a comprehensive overview of the current thinking on the causes, mechanisms, treatment and complications of diabetes.

Featured topics include:

- ☐ The causes of diabetic inheritance
- ☐ Immune factors of diabetes
- ☐ Mechanisms of diabetes (The culmination of 50 years of research)
- ☐ Autoimmunity
- ☐ New understandings in the mechanisms of insulin dependent and non-dependent diabetes mellitus
- ☐ New developments in the treatment of diabetes
- ☐ Methods of monitoring blood glucose and the use of glycosylated hemoglobin
- ☐ Pharmacology of oral hypoglycemics
- ☐ Use of insulin infusion devices
- ☐ Human insulin produced by recombinant DNA technology

If it is important to you in your practice to stay up-to-date on the latest developments in Diabetes Mellitus and you need a quick reference on the topic, then this is the book for you.

index increased. The time course of angiotensin II levels suggested that the lack of a cumulative effect from additive doses was a result of complete inhibition of converting enzyme. One patient did not respond to treatment with enalapril, despite comparable hemodynamic severity of heart failure, the renin angiotensin system was not activated. Thus, intravenous enalapril is capable of rapid and complete inhibition of converting enzyme for the accurate assessment of angiotensin II–mediated vasoconstriction in severe congestive heart failure. This may be helpful in clarifying the pathophysiologic characteristics of vasoconstriction for more specific therapy.

VALVULAR HEART DISEASE

127 Pattern of Left Ventricular Diastolic Filling in Chronic Aortic Regurgitation: A Gated Blood Pool Assessment

STEVEN J. LAVINE, WILLIAM P. FOLLANSBEE, DAVID P. SHREINER, VENKATARAMAN KRISHNASWAMI, P. S. REDDY, and KAREN S. McKEE

The left ventricular diastolic filling curve was evaluated in 24 normal subjects and 29 patients with chronic aortic regurgitation (AR). Reduced peak filling rates (PFR), mean filling rates (MFR), peak ejection rates (PER), PFR/MFR, PFR/PER, and a longer rapid filling period normalized for diastolic time was noted in patients with AR. Eight of the 29 patients with AR had clinical evidence of congestive heart failure. Diastolic filling values were abnormal in this subgroup compared with those in normal subjects, but were similar to those in the asymptomatic subgroup of patients with AR. In patients with AR, an abnormal pattern of diastolic filling was noted, consisting of reduced diastolic filling and systolic ejection rates with more linear filling (reduced PFR/MFR) during a longer rapid filling period.

133 Frequency of Mitral Valve Dysfunction from Mitral Anular Calcium as Detected by Doppler Echocardiography

ARTHUR J. LABOVITZ, JEANNE G. NELSON, DENISE M. WINDHORST, HAROLD L. KENNEDY, and GEORGE A. WILLIAMS

Fifty-one patients with echocardiographic diagnosis of mitral anular calcification (MAC) were examined by Doppler echocardiography to determine the prevalence of mitral regurgitation (MR) and functional mitral stenosis. Eleven patients (22%) were found to have mild MR, 17 patients (33%) moderate to severe MR, and 4 patients (8%) had significant mitral stenosis. Clinical descriptors such as heart murmur and history of congestive heart failure were of limited value in predicting hemodynamic abnormalities. Evaluation of transmitral flow by Doppler of patients with mitral anular calcium may be a useful adjunct in the noninvasive assessment of mitral valve flow.

138 Mitral Valve Prolapse and Ruptured Chordae Tendineae

ROBERT M. JERESATY, JESSE E. EDWARDS, and SURENDRA K. CHAWLA

To determine the causes of ruptured chordae tendineae and their possible etiologic relation to mitral valve prolapse, the mitral valve was examined in 25 consecutive and surgically proved cases of ruptured chordae tendineae. Mitral valve prolapse, in the absence of endocarditis, was the underlying pathologic abnormality in 22 of these 25 patients (88%). In 4 patients, mitral valve prolapse had been documented by auscultation before chordal rupture; none of these patients had had infective endocarditis. The morphologic and historical evidence suggests that mitral valve prolapse is probably the most common cause of ruptured chordae tendineae.

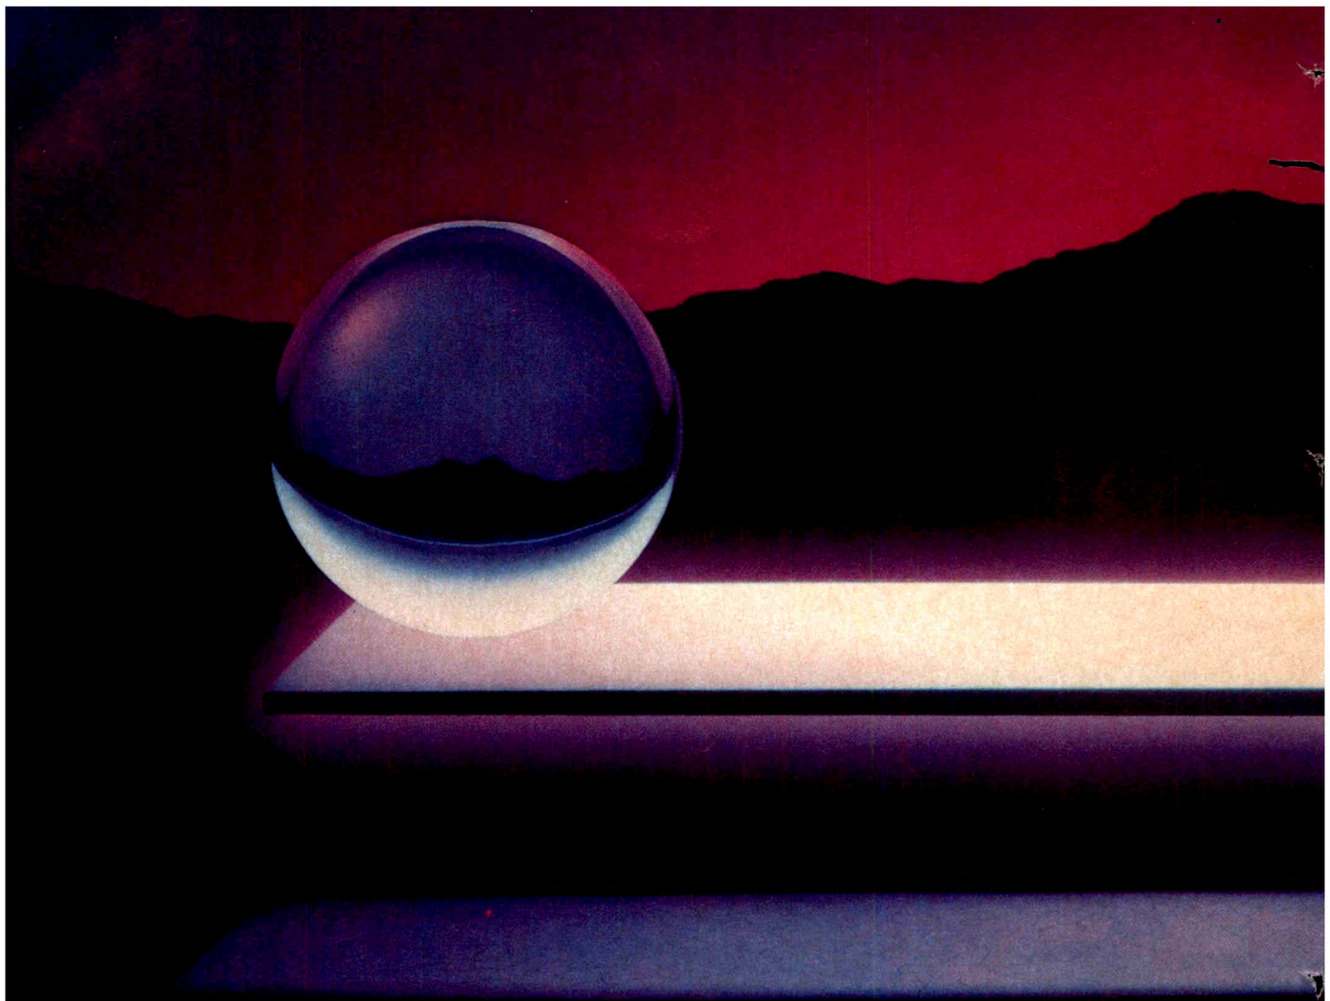
CARDIOMYOPATHY

143 Findings on Endomyocardial Biopsy in Infants and Children with Dilated Cardiomyopathy

ALAN B. LEWIS, HARRY B. NEUSTEIN, MASATO TAKAHASHI, and PAUL R. LURIE

Fifteen infants and children with dilated cardiomyopathy (DC) underwent transvascular endomyocardial biopsy. The light and electron microscopic findings were reviewed to assess the presence of lymphocytic infiltration indicating active myocarditis. Thirteen patients underwent both right and left ventricular biopsy and 2 underwent only right ventricular biopsy. An average of 5 tissue samples were obtained from each child. None of the endomyocardial biopsy specimens revealed an inflammatory process, despite evidence of extensive interstitial fibrosis, myofiber degeneration or hypertrophy. Ultrastructural changes in the mitochondria, T tubules or Z-band configuration were noted in approximately one-third of the patients. Thus, persistent, active myocarditis is an uncommon cause of DC in children. Immunosuppressive therapy, which may be harmful, should be considered in children with DC only after myocardial inflammation has been documented by endomyocardial biopsy.

Continued on page A44



TWO-WAY LIPID REGULATOR

LOPID® (gemfibrozil)

A Balanced Approach

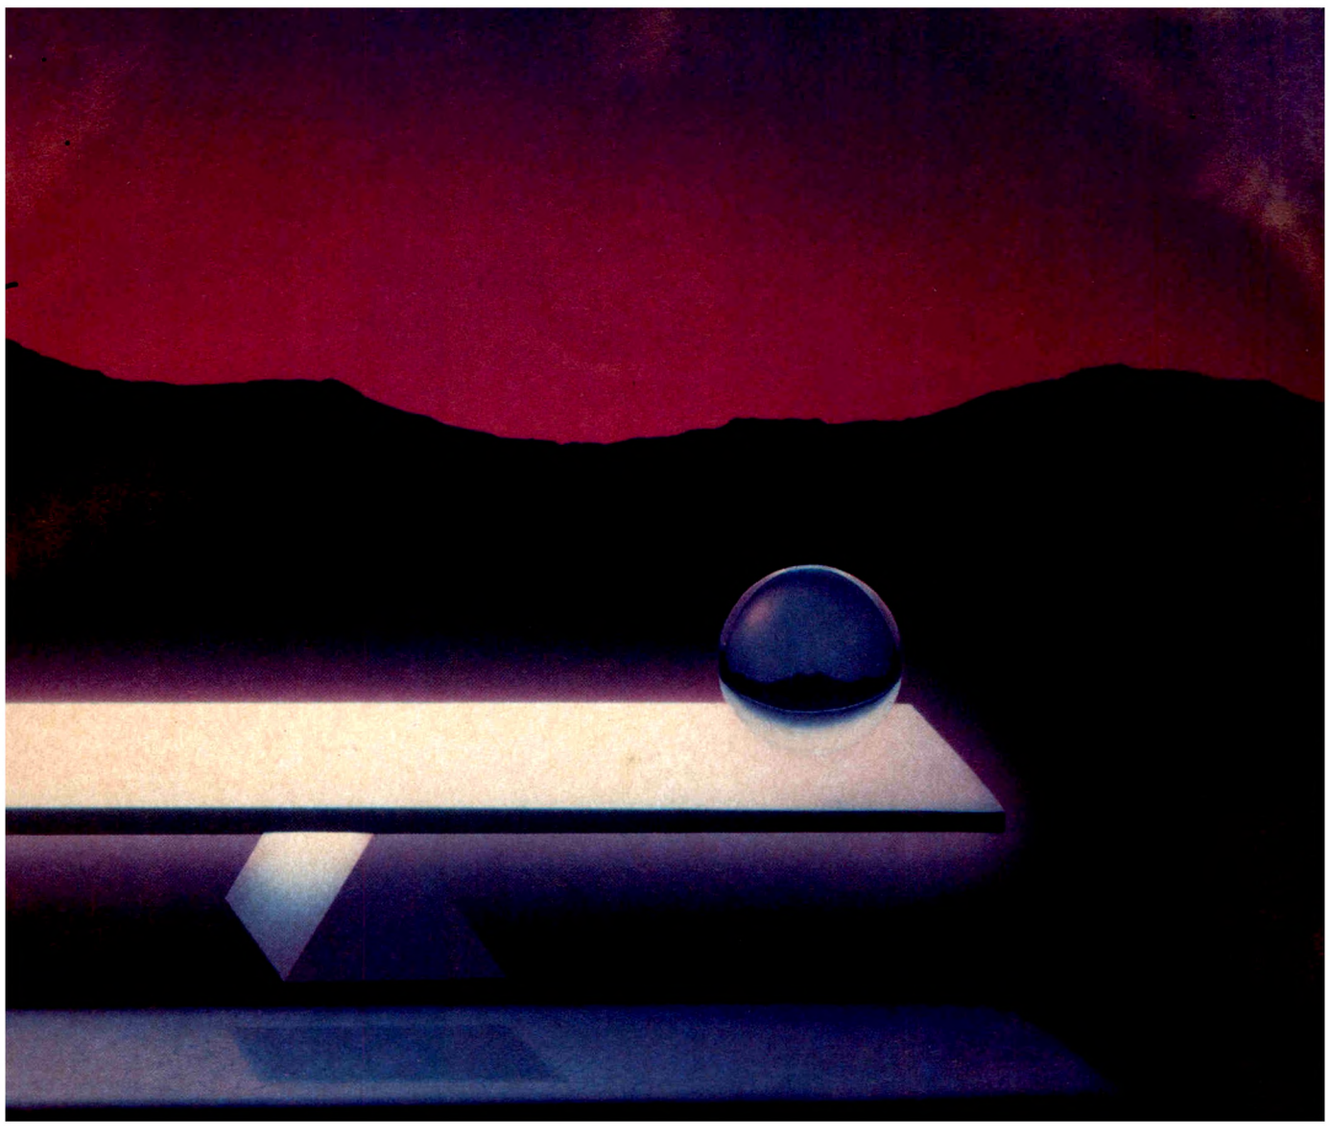
Favorably regulates the balance of lipoproteins responsible for transport of serum lipids.

LOPID is indicated for the treatment of adult patients with very high serum triglyceride levels (Type IV hyperlipidemia) who present a risk of pancreatitis and who do not respond adequately to diet.

Today, research continues to show that dyslipidemias do, in fact, involve more than high serum lipid levels (cholesterol and triglycerides). Underlying lipid disorders are an overproduction or faulty removal of some lipoproteins[1] and an underproduction of others.

LOPID® (gemfibrozil) does more than lower elevated serum lipids. LOPID helps correct the imbalance of lipoproteins seen in certain dyslipidemias...[2,3]

© 1984 Warner-Lambert Company



TWO-WAY LIPID REGULATOR

LOPID®

(gemfibrozil) 300-mg capsules

Before prescribing, please see full prescribing information.
A Brief Summary follows:

CLINICAL PHARMACOLOGY. LOPID is a lipid regulating agent which lowers elevated serum lipids primarily by decreasing serum triglyceride with a variable reduction in total serum cholesterol. These decreases occur primarily in the very low density lipoprotein (VLDL) fraction and less frequently in the low density lipoprotein (LDL) fraction. In addition, LOPID may increase the high density lipoprotein (HDL) cholesterol fraction, an action considered of possible benefit to inhibition of the atherosclerotic process.

The mechanism of action has not been definitively established. In man, LOPID has been shown to inhibit peripheral lipolysis and to decrease the hepatic extraction of free fatty acids, thus reducing hepatic triglyceride production. LOPID also inhibits synthesis of VLDL carrier apoprotein, leading to a decrease in VLDL production.

Animal studies suggest that LOPID may, in addition to elevating HDL cholesterol, reduce incorporation of long-chain fatty acids into newly formed triglycerides, accelerate turnover and removal of cholesterol from the liver, and increase excretion of cholesterol in the feces.

LOPID is well absorbed from the gastrointestinal tract after oral administration. Peak plasma levels occur in one to two hours with a plasma half-life of 1.5 hours following single doses and 1.3 hours following multiple doses. Plasma levels appear proportional to dose and do not demonstrate accumulation across time following multiple doses.

LOPID mainly undergoes oxidation of a ring methyl group to successively form a hydroxymethyl and a carboxyl metabolite. Approximately seventy percent of the administered human dose is excreted in the urine, primarily as unchanged gemfibrozil. Six percent of the dose is accounted for in the feces.

In a large, controlled multicenter trial of 427 patients, lipid and lipoprotein changes from average baseline (%) by hyperlipoproteinemic (HLP) type are summarized below for those patients receiving gemfibrozil, 1200 mg/day, at the end of 12 weeks.

HLP Type	TRIGLYCERIDE	CHOLESTEROL				RATIO
		Total	VLDL	LDL	HDL	HDL Cholesterol / Total Cholesterol
IIa	−44%	−4.2%	−44.3%	− 5.8%	+24.6%	+33%
IIb	−45%	−8.6%	−45.0%	− 6.4%	+19.5%	+34%
IV	−40%	−1.8%	−40.8%	+14.6%	+17.4%	+23%

INDICATIONS AND USAGE. Drug therapy should not be used for the routine treatment of elevated blood lipids for the prevention of coronary heart disease. Dietary therapy specific for the type of hyperlipidemia is the initial treatment of choice. Excess body weight and excess alcoholic intake may be important factors in hypertriglyceridemia and should be addressed prior to any drug therapy. Physical exercise can be an important ancillary measure. Contributory diseases such as hypothyroidism or diabetes mellitus should be looked for and adequately treated. The use of drugs should be considered only when reasonable attempts have been made to obtain satisfactory results with nondrug methods. If the decision is to use drugs, the patient should be instructed that this does not reduce the importance of adhering to diet.

Because of chemical, pharmacological, and clinical similarities between gemfibrozil and clofibrate, and the adverse findings with clofibrate in two large clinical studies (see Warnings), use of gemfibrozil should be restricted to the following indications.

LOPID may be considered for the treatment of adult patients with very high serum triglyceride levels (type IV hyperlipidemia) who present a risk of abdominal pain and pancreatitis and who do not respond adequately to a determined dietary effort to control them. Patients with triglyceride levels in excess of 750 mg per deciliter are likely to present such risk.

LOPID (gemfibrozil) has little effect on elevated cholesterol levels in most subjects. A minority of subjects show a more pronounced response. However, it must be understood that there is no evidence that use of any lipid-altering drug will be beneficial in preventing death from coronary heart disease (see WARNINGS). Therefore, the physician should be very selective and confine gemfibrozil treatment to patients with clearly defined risk due to severe hypercholesterolemia (eg, individuals with familial hypercholesterolemia starting in childhood) who inadequately respond to appropriate diet and more effective cholesterol-lowering drugs.

LOPID is not useful for the hypertriglyceridemia of Type I hyperlipidemia.

The biochemical response to gemfibrozil is variable, and it is not always possible to predict from the lipoprotein type or other factors which patients will obtain favorable results. It is essential that lipid levels be assessed and that the drug be discontinued after three months in any patient in whom lipids do not show significant improvement.

The effect of drug-induced reduction of serum cholesterol or triglyceride levels or elevation of HDL cholesterol levels on morbidity or mortality due to coronary heart disease has not been established. Several years may be required before ongoing long-term investigations will resolve this question.

CONTRAINDICATIONS. 1. Hepatic or severe renal dysfunction, including primary biliary cirrhosis.

2. Preexisting gallbladder disease. (See Warnings).

3. Hypersensitivity to gemfibrozil.

WARNINGS. 1. Because of chemical, pharmacological, and clinical similarities between gemfibrozil and clofibrate, the adverse findings with clofibrate in two large clinical studies may also apply to gemfibrozil. In the first of those studies, the Coronary Drug Project, 1000 subjects with previous myocardial infarction were treated for five years with clofibrate. There was no difference in mortality between the clofibrate-treated subjects and 3000 placebo-treated subjects, but twice as many clofibrate-treated subjects developed cholelithiasis and cholecystitis requiring surgery. In the other study, conducted by the World Health Organization, 5000 subjects without known coronary heart disease were treated with clofibrate for five years and followed one year beyond. There was a statistically significant 36% higher total mortality in the clofibrate-treated than in a comparable placebo-treated control group. The excess mortality was due to noncardiovascular causes, including malignancy, postcholecystectomy complications, and pancreatitis. The higher risk of clofibrate-treated subjects for gallbladder disease was confirmed.

2. Long-Term Toxicity and Animal Tumorigenicity Studies: Long-term studies have been conducted in rats and mice at one and ten times the human dose. The incidence of benign liver nodules and liver carcinomas was significantly increased in high dose male rats. The incidence of liver carcinomas increased also in low dose males, but this increase was not statistically significant (p greater than 0.05). There were no statistically significant differences from controls in the incidence of liver tumors in female rats, and in male and female mice.

Electron microscopy studies have demonstrated a florid hepatic peroxisome proliferation following LOPID administration to the male rat. Similar changes have not been found in the human liver.

Male rats had a dose-related increase of benign Leydig cell tumors. Subcapsular bilateral cataracts occurred in 10%, and unilateral in 6.3% of the high dose males.

3. Since a reduction of mortality from coronary artery disease has not been demonstrated and liver and interstitial cell testicular tumors were increased in male rats, LOPID should be administered only to those patients described in the Indications and Usage Section. If a significant serum lipid response is not obtained, LOPID should be discontinued.

4. Cholelithiasis—LOPID may increase cholesterol excretion into the bile leading to cholelithiasis. If cholelithiasis is suspected gallbladder studies are indicated. LOPID therapy should be discontinued if gallstones are found.

5. Concomitant Anticoagulants—Caution should be exercised when anticoagulants are given in conjunction with LOPID. The dosage of the anticoagulant should be reduced to maintain the prothrombin time at the desired level to prevent bleeding complications. Frequent prothrombin determinations are advisable until it has been definitely determined that the prothrombin level has stabilized.

PRECAUTIONS. 1. **Initial Therapy**—Before instituting LOPID (gemfibrozil) therapy, every attempt should be made to control serum lipids with appropriate diet, exercise, weight loss in obese patients, and other medical problems such as diabetes mellitus and hypothyroidism.

2. **Continued Therapy**—Pretreatment laboratory studies should be performed to ensure that patients have abnormal levels of serum lipids. Periodic determinations of serum lipids should be obtained during LOPID administration. The drug should be withdrawn after three months if the lipid response is inadequate.

3. **Seasonal Variation of Lipid Levels**—LOPID is not expected to alter seasonal variations of higher serum lipid values in mid-winter and late summer or the lower values in fall and spring.

4. **Impairment of Fertility**—Administration of approximately three and ten times the human dose to male rats for 10 weeks resulted in a dose-related decrease of fertility. Subsequent studies demonstrated that this effect was reversed after a drug-free period of about eight weeks, and it was not transmitted to their offspring.

5. **Pregnancy Category B**—Reproduction studies have been performed in the rat at doses 3 and 9 times the human dose, and in the rabbit at 2 and 6.7 times the human dose. These studies have revealed no evidence of impaired fertility in females or harm to the fetus due to LOPID. Minor fetotoxicity was manifested by reduced birth rates observed at the high dose levels. No significant malformations were found among almost 400 offspring from 36 litters of rats and 100 fetuses from 22 litters of rabbits.

There are no studies in pregnant women. In view of the fact that LOPID is tumorigenic in male rats, the use of LOPID in pregnancy should be reserved for those patients where the benefit clearly outweighs the possible risk to the patient or fetus.

6. **Nursing Mothers**—Because of the potential for tumorigenicity shown for gemfibrozil in male rats, a decision should be made whether to discontinue nursing or discontinue the drug, taking into account the importance of the drug to the mother.

7. **Hematologic Changes**—Mild hemoglobin, hematocrit and white blood cell decreases have been observed in occasional patients following initiation of LOPID therapy. However, these levels stabilize during long-term administration. Therefore, periodic blood counts are recommended during the first 12 months of LOPID administration.

8. **Liver Function**—Abnormal liver function tests have been observed occasionally during LOPID administration, including elevations of SGOT, SGPT, LDH, and alkaline phosphatase. These are usually reversible when LOPID is discontinued. Therefore periodic liver function studies are recommended and LOPID therapy should be terminated if abnormalities persist.

9. **Cardiac Arrhythmias**—Although no clinically significant abnormalities occurred that could be attributed to LOPID, the possibility exists that such abnormalities may occur.

10. **Use in Children**—Safety and efficacy in children have not been established.

ADVERSE REACTIONS. In controlled clinical trials of 805 patients, including 245 who received LOPID for at least one year, the most frequently reported adverse reactions associated with LOPID involved the gastrointestinal system. In decreasing order of frequency, these were abdominal pain (6.0%), epigastric pain (4.9%), diarrhea (4.8%), nausea (4.0%), vomiting (1.6%), and flatulence (1.1%). Other adverse reactions where the probability of a causal relationship to LOPID therapy exists are listed by system.

Integumentary: rash, dermatitis, pruritus, urticaria
Central Nervous System: headache, dizziness, blurred vision
Musculoskeletal: painful extremities
Hematopoietic: anemia, eosinophilia, leukopenia

Other reactions have been reported under conditions where a causal relationship is difficult to establish, thus the physician should be alert to these occurrences. Reports of viral and bacterial infections (common cold, cough, and urinary tract infections) were more common in gemfibrozil than in placebo-treated patients.

Other reactions were:
Gastrointestinal: dry mouth, constipation, anorexia, gas pain, dyspepsia
Musculoskeletal: back pain, arthralgia, muscle cramps, myalgia, swollen joints
Central Nervous System: vertigo, insomnia, paresthesia, tinnitus
Clinical Laboratory: hypokalemia, liver function abnormalities (increased SGOT, SGPT, LDH, CPK, alkaline phosphatase)
Miscellaneous: fatigue, malaise, syncope

DOSAGE AND ADMINISTRATION. The recommended dose for adults is 1200 mg administered in two divided doses 30 minutes before the morning and evening meal. Some patients will experience therapeutic effects on 900 mg/day; a few may require 1500 mg/day for satisfactory results.

DRUG INTERACTIONS. CAUTION SHOULD BE EXERCISED WHEN ANTICOAGULANTS ARE GIVEN IN CONJUNCTION WITH LOPID (GEMFIBROZIL). THE DOSAGE OF THE ANTICOAGULANT SHOULD BE REDUCED TO MAINTAIN THE PROTHROMBIN TIME AT THE DESIRED LEVEL TO PREVENT BLEEDING COMPLICATIONS. FREQUENT PROTHROMBIN DETERMINATIONS ARE ADVISABLE UNTIL IT HAS BEEN DEFINITELY DETERMINED THAT THE PROTHROMBIN LEVEL HAS STABILIZED.

MANAGEMENT OF OVERDOSAGE. While there has been no reported case of overdosage, symptomatic supportive measures should be taken should it occur.

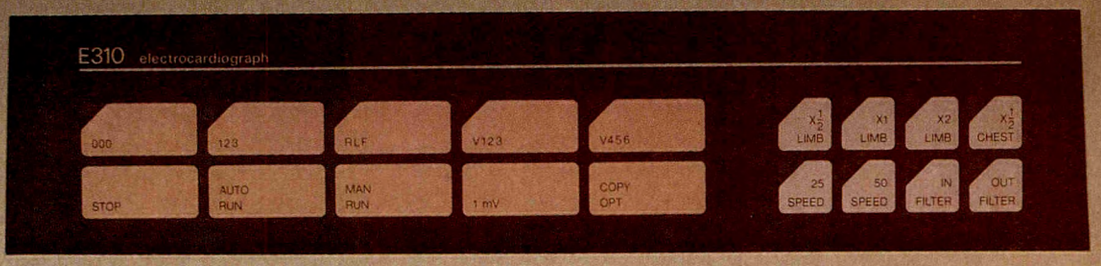
WHY PAY FOR MORE THAN YOU USE? BURDICK'S E 310



The high-volume E310 from Burdick was designed to supply only the most-commonly used functions of a three-channel electrocardiograph. So you don't pay for all those features you never use.

Simplicity was also designed into the E310. A glance at the control panel will tell you so. Just press Auto Run, and E310 will run through all classical lead groups. Press the Copy touch pad, and E310 will make diagnostically accurate copies of the last electrocardiogram — as many as you need.

So why pay for more 3-channel electrocardiograph than you use? E310 is three-channel simplicity. Call for a demonstration.

E310 — another value from the growing Burdick family.

146 **Arrhythmias in Ischemic and Nonischemic Dilated Cardiomyopathy: Prediction of Mortality by Ambulatory Electrocardiography**

JOHN HOLMES, SPENCER H. KUBO, ROBERT J. CODY, and PAUL KLIGFIELD

The prognostic value of the frequency and complexity of ventricular ectopy was evaluated in 31 patients with severe ischemic and nonischemic dilated cardiomyopathy who underwent right-sided cardiac catheterization and neurohormonal profiling. Subgroups based on peak ventricular arrhythmia grade included 9 patients with simple ventricular premature contractions (Lown 1 to 3) and 22 patients with complex ventricular premature contractions (Lown 4 and 5). During the 14-month mean follow-up period, 14 patients died, 12 from sudden death and 2 in circulatory failure. Mortality was strikingly related to arrhythmias: The mortality rate was 11% in the simple ventricular arrhythmia group and 59% in the complex ventricular arrhythmia group. No baseline variable other than peak ventricular premature contraction grade so clearly predicted death. These data are consistent with the hypothesis that complex ventricular arrhythmias represent an independent mortality risk factor in patients with severe dilated cardiomyopathy.

CONGENITAL HEART DISEASE

152 **Value of Image Enhancement and Injection of Contrast Medium for Right Ventricular Volume Determination by Two-Dimensional Echocardiography in Congenital Heart Disease**

PETER E. LANGE, PETER A. SEIFFERT, FRANK PREIS, ARMIN WESSEL, DIETRICH G. W. ONNASCH, HANS-J. HAHNE, and PAUL H. HEINTZEN

Right ventricular volumes calculated on the basis of echocardiographic cross sections from 23 children before and after application of digital enhancement techniques underestimated angiocardiographic volumes ($p < 0.01$) and more so in end-diastole (51%) than in end-systole (36%). Correlation between angio- and echocardiographic volumes was good for end-diastole and end-systole for the unprocessed echograms ($r = 0.97/0.95$), after image enhancement ($r = 0.97/0.96$), and after image enhancement and injection of contrast media ($r = 0.97/0.95$). The echocardiographic 4-chamber view allows right ventricular volume determination with an acceptable accuracy; its underestimation is related to inadequate visualization of trabeculations and mainly to the model used. Application of image enhancement techniques allows easier outlining of the internal cavity surface but does not improve the accuracy significantly. The advantage gained by the combination of contrast injection and image enhancement techniques does not warrant the routine central injection of available contrast material.

MISCELLANEOUS TOPICS

159 **Magnitude and Implications of Spontaneous Hemodynamic Variability in Primary Pulmonary Hypertension**

STUART RICH, GILBERT E. D'ALONZO, DAVID R. DANTZKER, and PAUL S. LEVY

The pulmonary artery (PA) pressure at rest and pulmonary resistance may vary in patients with primary pulmonary hypertension (PPH). We determined the amount of variability (coefficient of variation) in the systemic and PA pressure, cardiac output and systemic and pulmonary resistance by making hourly measurements for 6 hours in 12 patients with PPH. Then, the patients underwent hydralazine and nifedipine treatment and the percent decrease in pulmonary resistance was measured. Spontaneous variability occurred in every patient, averaging 8% in PA pressure and 13% in pulmonary resistance. Patients with the most variability in PA pressure had the most variability in cardiac output ($r = 0.69$, $p = 0.02$) and variability was greatest in patients who had the highest pulmonary resistances ($r = 0.91$, $p < 0.01$). There was no correlation between the amount of variability and the decrease in pulmonary resistance from hydralazine or nifedipine. From these data, we derived 95% confidence limits and calculated that a change of 22% in PA pressure, or 36% in pulmonary resistance would be necessary in order to attribute the changes to a drug effect in a given patient.

164 **Acute Effects of Alcohol on Left Ventricular Function in Healthy Subjects at Rest and During Upright Exercise**

HENNING KELBAEK, THOMAS GJØRUP, INGELISE BRYNJOLF, NIELS JUEL CHRISTENSEN, and JOHN GODTFREDSEN, *With the technical assistance of* BIRGIT VESTERGAARD

Radionuclide angiocardiography was performed in 6 healthy men, median age 25 years, at rest and at submaximal exercise during light (serum ethanol 23 mmol/liter) and heavy (serum ethanol 45 mmol/liter) alcohol intoxication. At light intoxication, left ventricular ejection fraction at rest decreased (5%). At heavy intoxication left ventricular ejection fraction decreased both at rest (11%) and at 75% submaximal exercise (6%), heart rate at rest increased (81 vs 62 beats/min), and systolic blood pressure decreased at 50% submaximal exercise (145 vs 163 mm Hg). Plasma-norepinephrine concentrations were increased by 24% during light and by 30 to 38% during heavy intoxication; no changes were recorded in plasma epinephrine concentrations. Control investiga-

PREDICTABILITY IN A B.I.D. DOSAGE

Norpace® CR

(disopyramide phosphate)

CONTROLLED-RELEASE 100-mg and 150-mg 12-HOUR CAPSULES

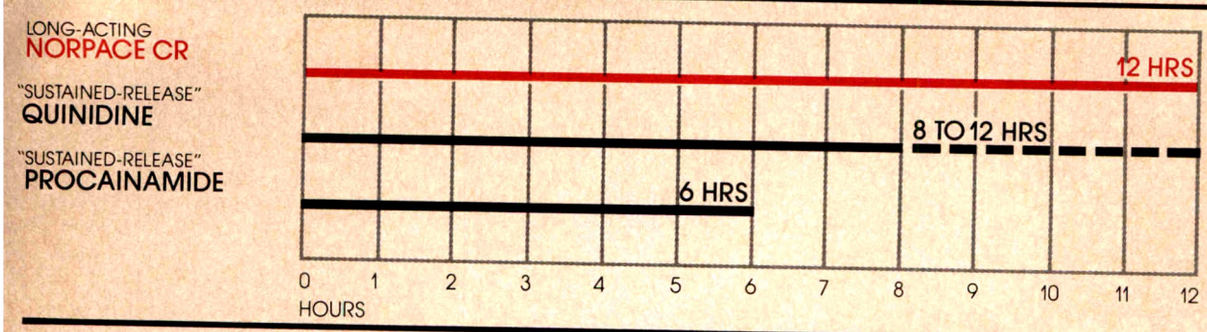
The most commonly seen side effects of disopyramide phosphate are anticholinergic, and the most severe are due to its negative inotropic properties.

Please see next page for a brief summary of the complete prescribing information.

SEARLE

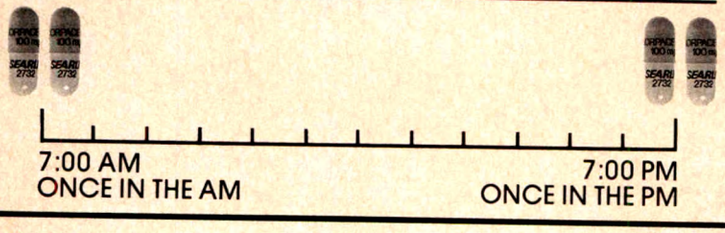
PREDICTABILITY IN A B.I.D. DOSAGE

DURATION OF ANTIARRHYTHMIC ACTION



Norpace® CR
(disopyramide phosphate)

CONTROLLED-RELEASE 100-mg and 150-mg 12-HOUR CAPSULES



Brief Summary

Before prescribing, please consult current complete prescribing information, a summary of which follows: **Indications:** For suppression and prevention of recurrence of the following cardiac arrhythmias: unifocal premature (ectopic) ventricular contractions; premature (ectopic) ventricular contractions of multifocal origin; paired premature ventricular contractions (couplets); and episodes of ventricular tachycardia (persistent ventricular tachycardia is ordinarily treated with D.C. cardioversion). Norpace is equally effective in both digitalized and nondigitalized patients. It is also equally effective in treating primary cardiac arrhythmias and those which occur in association with organic heart disease including coronary artery disease. Norpace CR should not be used initially if rapid establishment of disopyramide plasma levels is desired. Oral disopyramide phosphate has not been adequately studied in patients with acute myocardial infarction or with persistent ventricular tachycardia or atrial arrhythmias and is not indicated for arrhythmias due to digitalis intoxication. The value of antiarrhythmic drugs in preventing sudden death in patients with serious ventricular ectopic activity has not been established. **Contraindications:** Cardiogenic shock, preexisting second- or third-degree AV block (if no pacemaker is present), or known hypersensitivity to the drug. **Warnings: Norpace or Norpace CR may cause or worsen congestive heart failure (CHF) or produce severe hypotension as a consequence of its negative inotropic properties. Hypotension has been observed primarily with primary cardiomyopathy or inadequately compensated CHF. Norpace or Norpace CR should not be used in patients with uncompensated or marginally compensated CHF or hypotension unless the condition is secondary to cardiac arrhythmia. Patients with a history of heart failure may be treated with Norpace or Norpace CR, but careful attention must be given to maintaining cardiac function, including optimal digitalization. If hypotension occurs or CHF worsens, Norpace or Norpace CR should be discontinued and, if necessary, restarted at a lower dosage only after adequate cardiac compensation has been established. Norpace or Norpace CR should be discontinued if significant widening (greater than 25%) of the QRS complex occurs. Prolongation of the Q-T interval (corrected) and worsening of the arrhythmia may occur. Patients who have evidenced prolongation of the Q-T interval in response to quinidine may be at particular risk. If Q-T prolongation greater than 25% is observed and if ectopy continues, the patients should be monitored closely, and discontinuation of Norpace or Norpace CR considered. In rare instances significant hypoglycemia has been reported during Norpace therapy. The concomitant use of Norpace or Norpace CR with other Type 1 antiarrhythmic agents and/or propranolol should be reserved for patients with life-threatening arrhythmias who are demonstrably unresponsive to single agent antiarrhythmic therapy. Such use may produce serious negative inotropic effects, or may excessively prolong conduction. Patients receiving more than one antiarrhythmic drug must be carefully monitored. If first-degree heart block develops, the dosage of Norpace or Norpace CR should be reduced. If the block persists, continuation of Norpace or Norpace CR must depend upon an assessment of benefit versus risk. Development of second- or third-degree AV block or uni-, bi-, or trifascicular block requires discontinuation of drug unless the ventricular rate is adequately controlled by a pacemaker. Because of its anticholinergic activity, disopyramide phosphate should not be used in patients with glaucoma, myasthenia gravis or urinary retention, unless adequate overriding measures are taken. In patients with a family history of glaucoma, intraocular pressure should be measured before initiating Norpace or Norpace CR therapy. Precautions:** Patients with atrial flutter or fibrillation should be digitalized prior to Norpace or Norpace CR administration to ensure that drug-induced enhancement of AV conduction does not allow a ventricular rate beyond physiologically acceptable limits. The effect of Norpace or Norpace CR is presently uncertain in patients with sick sinus syndrome, Wolff-Parkinson-White syndrome, or bundle branch block. Patients with myocarditis or other cardiomyopathy may develop significant hypotension in response to the usual dosage of disopyramide phosphate. Therefore, a loading dose of Norpace should not be given to such patients, and initial dosage and subsequent dosage adjustments should be made under close supervision. Norpace dosage should be reduced in patients with impaired renal or hepatic function and the electrocardiogram carefully monitored for signs of overdosage. Norpace CR is not recommended for patients with severe renal insufficiency. Antiarrhythmic drugs may be ineffective in patients with hypokalemia, and their toxic effects may be enhanced in patients with hyperkalemia. Therefore, potassium abnormalities should be corrected before starting Norpace or Norpace CR therapy. Concomitant administration of disopyramide phosphate with phenytoin or other hepatic enzyme inducers may cause lower disopyramide plasma levels. Safe use in pregnancy has not been established. Disopyramide has been found in human fetal blood. **Norpace has been reported to stimulate contractions of the pregnant uterus.** Use of Norpace or Norpace CR in pregnant women requires that the potential benefit be weighed against possible hazards to the fetus. Effects of Norpace or Norpace CR on the fetus during delivery or on the course of labor and delivery are unknown. Following oral administration, disopyramide has been found in human milk at a concentration not exceeding that in plasma. If use of the drug is deemed essential, an alternate method of infant feeding should be instituted. **Adverse Reactions:** Dry mouth, urinary hesitancy, constipation, blurred vision, dry nose/eyes/throat, urinary retention especially in males with benign prostatic hypertrophy, urinary frequency and urgency, impotence, nausea, pain/bloating/gas, anorexia, diarrhea, vomiting, nervousness, dizziness, general fatigue/muscle weakness, headache, malaise, aches/pains, hypotension, congestive heart failure, cardiac conduction disturbances, edema/weight gain, shortness of breath, syncope, chest pain, generalized rash/dermatoses, itching, hypokalemia, elevated cholesterol/triglycerides, depression, insomnia, dysuria, numbness/tingling, elevated liver enzymes, AV block, elevated BUN, elevated creatinine, decreased hemoglobin/hematocrit, and hypoglycemia. Acute psychosis, cholestatic jaundice, and agranulocytosis, all three reversible, have been reported, as have fever, respiratory difficulty, thrombocytopenia, and gynecomastia. **Dosage and Administration:** Dosage must be individualized on the basis of response and tolerance. The usual adult dosage is 400 to 800 mg/day given in divided doses: q6h for Norpace and q12h for Norpace CR. **See current complete prescribing information for dosage recommendations.**

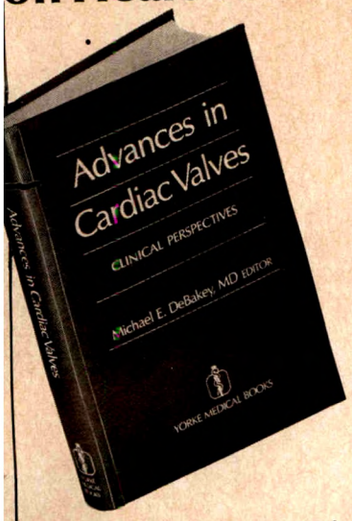
The Most Extensive Compilation of Information on Heart Valve Replacement Available Today!



Advances in Cardiac Valves
Clinical Perspectives

edited by **Michael E. DeBakey, MD**

0-914316-40-0, November 1983, 274pp., $35.00

This valuable new clinical reference provides a detailed update on many aspects of mechanical heart valve prostheses, including hemodynamics, clinical results, results in children, non-invasive assessments, special indications, and implant techniques. Each topic is presented in an easily understood style and format which facilitate the comprehension of recent developments in heart valve replacement for the busy clinician.

Each chapter is written by internationally respected physicians and medical scientists each of whom is pre-eminent in his field. All of this information has been co-ordinated by Dr. DeBakey to produce a very readable and informative volume on the state-of-the-art of heart valve replacement with mechanical prostheses. No cardiologist, cardiovascular surgeon, internist, or bioengineer can afford *not* to be knowledgeable about th information in this book.

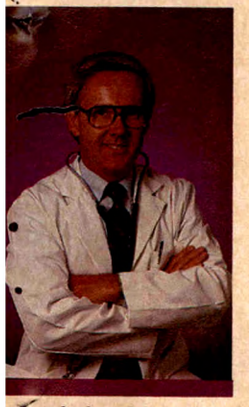
TELECTRONICS
"Reliably pacing
the world
since 1962."

Selecting a pacemaker company is no easy task.



We know.

We've asked numerous physicians what qualities they expect from a company. Many physicians select a company that offers a complete range of high quality, reliable products. Others seek a company with innovative, sophisticated products, backed by a strong commitment to R & D. Still others seek support services, such as; knowledgeable sales reps, educational programs and technical training.

We know because at Telectronics, we've been providing quality products and services to physicians for more than 20 years. Until recently, however, we've been a little too quiet about our accomplishments. We believe it's to your advantage to understand more about what Telectronics offers you.

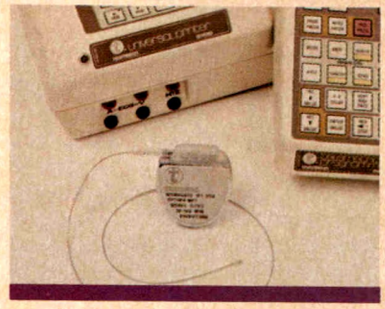
Years of innovation.

Our commitment to Research & Development started back in 1962...we were first with the energy-saving 0.5ms pacing pulse. First with hermetically sealed, titanium encapsulation. First with monolithic circuitry. First in antitachycardia pacing...we are dedicated to advanced technology to provide you with the products you need to give the best care possible.

A quarter of a century of reliability.

Today, as always, our product quality and reliability is second to none. In every aspect of the design and manufacture of our product, our most important consideration is providing product of the highest quality. Our dual chamber generators are setting the standards in the most advanced area of pacing. In fact, the latest report of achievable reliability for our second generation DDD pacemaker reveals a survival rate over 99%*. Telectronics means reliability.

Simple, sophisticated pacing.



As your needs have grown more sophisticated, we have advanced our technologies to keep pace. Telectronics offers quality pacing products to fulfill all your requirements... leads, generators, analyzers, programmers and printers. A complete line of reliable pacing systems designed for easy use.

24 Hour service, worldwide.

In 42 countries around the world, we are ready to meet your needs. At Telectronics, we offer a variety of services to aid you in your practice. Such as; clinical and technical training, troubleshooting, readily available emergency stock, and most importantly, experienced sales representatives with extensive product knowledge. At any hour of the day, wherever you are, you have our undivided attention and support.

Quality. Innovation. Reliability. Service.

These are the ideals Telectronics has been built on. The commitment to these ideals is our foundation for the future. If these ideals are as important to you, then we invite you to come share the pacing future with us.

TELECTRONICS

Reliably pacing the world today...and tomorrow.

*Reliability report available on request.

a member of the NUCLEUS group

tions revealed no significant changes in measurements due to ingestion of isovolumic, isocaloric drinks. It is suggested that alcohol intoxication causes a dose-dependent impairment of cardiac contractility. Compensatory mechanisms may account for a reduced influence during exercise.

168 **Diastolic Time During Recovery from Upright Exercise in Persons Without Heart Disease**

TETSURO SUGIURA, TOSHIJI IWASAKA, YOSHINORI L. DOI, BRUCE G. HAFFTY, MITSUO INADA, and DAVID H. SPODICK

In 12 normal volunteers, despite decreased heart rate at 5 and 2 minutes after exercise in the upright position, diastolic time and total diastole per minute shortened significantly, with disproportionate lengthening of diastolic time at 2 minutes. These events appear to represent a physiologic response due to increased ventricular filling in the presence of diminishing adrenergic effect.

171 **Radiation Exposure and Protection in Cardiac Catheterization Laboratories**

STEPHEN W. MILLER and FRANK P. CASTRONOVO, Jr.

This report is a review of the literature regarding radiation exposure and protection in cardiac catheterization laboratories. Cardiac catheterization with angiography may give a patient the largest dose of x-radiation of any diagnostic medical examination. In contrast, the physicians and technologists working daily in the catheterization laboratory receive low-level radiation over an extended time period. Although the radiobiology is complex, the physicians who perform cardiac catheterization should be familiar with potential genetic and somatic effects and with the methods to reduce or eliminate radiation exposure. Catheterization personnel have control over the time duration of exposure, placement of technologists, shielding and dosimetry.

METHODS

177 **Accuracy of Left Ventricular Ejection Fraction Using the Nuclear Stethoscope in Left Ventricular Aneurysm**

DAVID M. McCARTHY and P. TODD MAKLER, Jr.

Although the nuclear stethoscope, a nonimaging probe, accurately determines left ventricular (LV) ejection fraction (EF), its reliability in patients with LV aneurysm has not been established. Accordingly, LVEF was determined using the nuclear stethoscope and compared with that determined by equilibrium gated blood pool scanning in 29 patients, 1 studied on 2 separate occasions, for a total of 30 patient studies. Patient studies were separated into 2 groups. Patients in group I ($n = 20$) had no gated blood pool evidence for aneurysm, and those in group II ($n = 10$) had discrete focal akinesia or dyskinesia. Nineteen patients (13 in group I and 6 in group II) had 2 separate nuclear stethoscope acquisitions. In group I, EF determined by gated blood pool scanning ($53 \pm 4\%$, mean $\pm$ standard error) did not differ from that determined by nuclear stethoscope ($51 \pm 4\%$). EF determined using either gated blood pool scanning ($32 \pm 6\%$) or nuclear stethoscope ($35 \pm 5\%$) was significantly lower in group II than in group I, although nuclear stethoscope and gated blood pool scanning did not differ. Reproducibility was excellent ($r = 0.96$). Overall, nuclear stethoscope and gated blood pool EFs correlated closely ($r = 0.93$), and the correlation coefficients were similar in groups I ($r = 0.92$) and II ($r = 0.92$). The slopes of the regression curve for group I (0.97) and group II (0.92) were not statistically different. These results confirm the accuracy and reproducibility of LVEF determination by nuclear stethoscope and specifically demonstrate its reliability in patients with LV aneurysm.

CARDIOVASCULAR PHARMACOLOGY

181 **Association of Methemoglobinemia and Intravenous Nitroglycerin Administration**

KERRY J. KAPLAN, MARK TABER, J. RUSSELL TEAGARDEN, MICHELE PARKER, and RICHARD DAVISON

Significant elevation of arterial methemoglobin levels has been reported with the administration of intravenous (i.v.) nitroglycerin (NTG). To determine the incidence and clinical significance of this potential side effect of i.v. NTG, serial arterial methemoglobin levels were determined in 50 consecutive patients who received i.v. NTG for at least 48 hours. The mean methemoglobin level for the 141 samples was $1.57 \pm 0.08\%$, which differs from the control mean value in our laboratory of $0.44 \pm 0.01\%$. Although no patients had clinical symptoms from methemoglobin, 20 patients had elevated levels ($>1\%$) on at least 1 occasion. Seventy-eight of the 141 samples analyzed were in the normal range, whereas the other 63 determinations were between 2 and 5%. Patients with normal methemoglobin levels differed from those with abnormal levels in the dose of i.v. NTG (mean infusion rate 244 ± 16 vs 351 ± 17 μg/min; total cumulative dose $1,612 \pm 153$ vs $3,398 \pm 308$ mg). In conclusion, clinically significant methemoglobinemia is uncommon with i.v. NTG infusion; however, when large doses of NTG are administered, this complication is more likely.

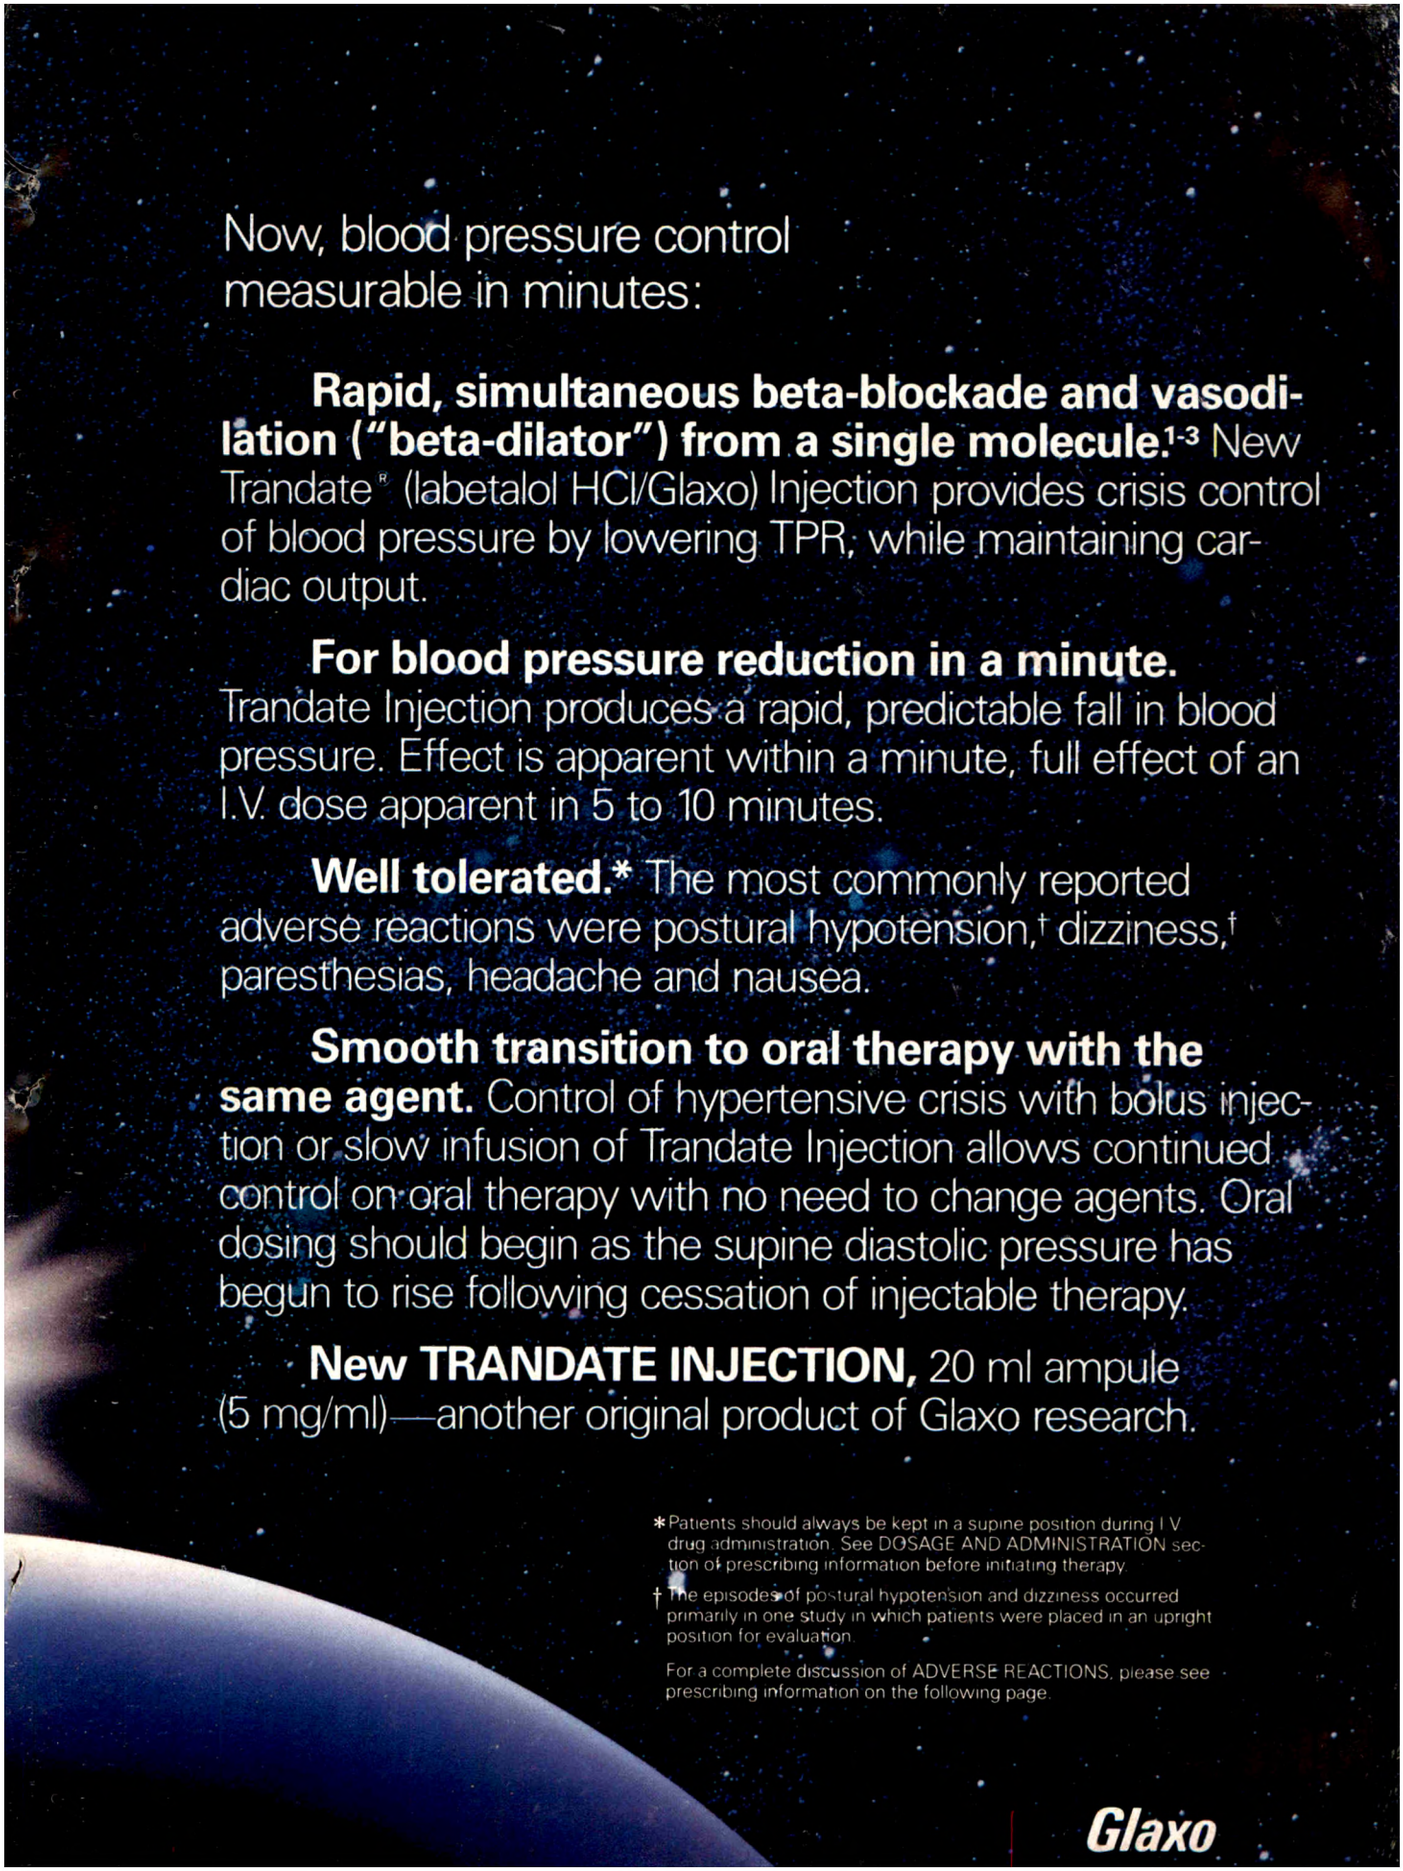
TRANDATE®
INJECTION
labetalol HCl/Glaxo
for hypertensive emergencies
Another original product of Glaxo research.
Glaxo

New
TRANDATE®
INJECTION
labetalol HCl/Glaxo
the world's first
"beta-dilator"™
for hypertensive
emergencies



Now, blood pressure control
measurable in minutes:
Rapid, simultaneous beta-blockade and vasodilation ("beta-dilator") from a single molecule.[1-3] New Trandate® (labetalol HCl/Glaxo) Injection provides crisis control of blood pressure by lowering TPR, while maintaining cardiac output.
For blood pressure reduction in a minute. Trandate Injection produces a rapid, predictable fall in blood pressure. Effect is apparent within a minute, full effect of an I.V. dose apparent in 5 to 10 minutes.
Well tolerated.* The most commonly reported adverse reactions were postural hypotension,† dizziness,† paresthesias, headache and nausea.
Smooth transition to oral therapy with the same agent. Control of hypertensive crisis with bolus injection or slow infusion of Trandate Injection allows continued control on oral therapy with no need to change agents. Oral dosing should begin as the supine diastolic pressure has begun to rise following cessation of injectable therapy.
New TRANDATE INJECTION, 20 ml ampule (5 mg/ml)—another original product of Glaxo research.
*Patients should always be kept in a supine position during I.V. drug administration. See DOSAGE AND ADMINISTRATION section of prescribing information before initiating therapy.
† The episodes of postural hypotension and dizziness occurred primarily in one study in which patients were placed in an upright position for evaluation.
For a complete discussion of ADVERSE REACTIONS, please see prescribing information on the following page.
Glaxo

TRANDATE® Injection
(labetalol hydrochloride)

BRIEF SUMMARY OF PRESCRIBING INFORMATION

INDICATIONS AND USAGE

TRANDATE® (labetalol HCl) Injection is indicated for control of blood pressure in severe hypertension.

CONTRAINDICATIONS

TRANDATE® (labetalol HCl) Injection is contraindicated in bronchial asthma, overt cardiac failure, greater than first degree heart block, cardiogenic shock, and severe bradycardia (see WARNINGS).

WARNINGS

Cardiac Failure Sympathetic stimulation is a vital component supporting circulatory function in congestive heart failure. Beta blockade carries a potential hazard of further depressing myocardial contractility and precipitating more severe failure. Although beta-blockers should be avoided in overt congestive heart failure, if necessary, labetalol HCl can be used with caution in patients with a history of heart failure who are well-compensated. Congestive heart failure has been observed in patients receiving labetalol HCl. Labetalol HCl does not abolish the inotropic action of digitalis on heart muscle.

In Patients Without a History of Cardiac Failure In patients with latent cardiac insufficiency, continued depression of the myocardium with beta-blocking agents over a period of time can in some cases lead to cardiac failure. At the first sign or symptom of impending cardiac failure, patients should be fully digitalized and/or be given a diuretic, and the response observed closely. If cardiac failure continues, despite adequate digitalization and diuretic, TRANDATE® (labetalol HCl) therapy should be withdrawn (gradually, if possible).

Ischemic Heart Disease Angina pectoris has not been reported upon labetalol HCl discontinuation. However, following abrupt cessation of therapy with some beta-blocking agents in patients with coronary artery disease, exacerbations of angina pectoris and, in some cases, myocardial infarction have been reported. Therefore, such patients should be cautioned against interruption of therapy without the physician's advice. Even in the absence of overt angina pectoris, when discontinuation of TRANDATE (labetalol HCl) is planned, the patient should be carefully observed and should be advised to limit physical activity. If angina markedly worsens or acute coronary insufficiency develops, TRANDATE (labetalol HCl) administration should be reinstituted promptly, at least temporarily, and other measures appropriate for the management of unstable angina should be taken.

Nonallergic Bronchospasm (e.g., chronic bronchitis and emphysema) Since TRANDATE (labetalol HCl) Injection at the usual intravenous therapeutic doses has not been studied in patients with nonallergic bronchospastic disease, it should not be used in such patients.

Pheochromocytoma Intravenous labetalol HCl has been shown to be effective in lowering the blood pressure and relieving symptoms in patients with pheochromocytoma; higher than usual doses may be required. However, paradoxical hypertensive responses have been reported in a few patients with this tumor; therefore, use caution when administering labetalol HCl to patients with pheochromocytoma.

Diabetes Mellitus and Hypoglycemia Beta-adrenergic blockade may prevent the appearance of premonitory signs and symptoms (e.g., tachycardia) of acute hypoglycemia. This is especially important with labile diabetics. Beta blockade also reduces the release of insulin in response to hypoglycemia; it may therefore be necessary to adjust the dose of antidiabetic drugs.

Major Surgery The necessity or desirability of withdrawing beta-blocking therapy prior to major surgery is controversial. Protracted severe hypotension and difficulty in restarting or maintaining a heart beat have been reported with beta-blockers. The effect of labetalol HCl's alpha-adrenergic activity has not been evaluated in this setting.

A synergism between labetalol HCl and halothane anesthesia has been shown (see Drug Interactions under PRECAUTIONS).

Rapid Decreases of Blood Pressure Caution must be observed when reducing severely elevated blood pressure. Although such findings have not been reported with intravenous labetalol HCl, a number of adverse reactions, including cerebral infarction, optic nerve infarction, angina and ischemic changes in the electrocardiogram, have been reported with other agents when severely elevated blood pressure was reduced over time courses of several hours, to as long as one or two days. The desired blood pressure lowering should therefore be achieved over as long a period of time as is compatible with the patient's status.

PRECAUTIONS

General *Impaired Hepatic Function* may diminish metabolism of TRANDATE® (labetalol HC., Injection.

Hypotension Symptomatic postural hypotension (incidence 58%) is likely to occur if patients are tilted or allowed to assume the upright position within 3 hours of receiving TRANDATE (labetalol HCl) Injection. Therefore, the patient's ability to tolerate an upright position should be established before permitting any ambulation.

Jaundice or Hepatic Dysfunction On rare occasions, oral labetalol HCl has been associated with jaundice (both hepatic and cholestatic). It is therefore recommended that treatment with labetalol HCl be stopped immediately, should a patient develop jaundice or laboratory evidence of liver injury. Both have been shown to be reversible on stopping therapy.

Information for Patients

The following information is intended to aid in the safe and effective use of this medication. It is not a disclosure of all possible adverse or intended effects. During and immediately following (for up to 3 hours) TRANDATE (labetalol HCl) Injection, the patient should remain supine. Subsequently, the patient should be advised on how to proceed gradually to become ambulatory, and should be observed at the time of first ambulation.

When the patient is started on TRANDATE Tablets, following adequate control of blood pressure with TRANDATE Injection, appropriate directions for titration of dosage should be provided. (see DOSAGE AND ADMINISTRATION).

As with all drugs with beta-blocking activity, certain advice to patients being treated with labetalol HCl is warranted: While no incident of the abrupt withdrawal phenomenon (exacerbation of angina pectoris) has been reported with labetalol HCl, dosing with TRANDATE Tablets should not be interrupted or discontinued without a physician's advice. Patients being treated with TRANDATE Tablets should consult a physician at any sign of impending cardiac failure. Also, transient scalp tingling may occur, usually when treatment with TRANDATE Tablets is initiated (see ADVERSE REACTIONS).

Laboratory Tests

Routine laboratory tests are ordinarily not required before or after intravenous labetalol HCl. In patients with concomitant illnesses, such as impaired renal function, appropriate tests should be done to monitor these conditions.

Drug Interactions

Since TRANDATE (labetalol HCl) Injection may be administered to patients already being treated with other medications, including other antihypertensive agents, careful monitoring of these patients is necessary to detect and treat promptly any undesired effect from concomitant administration.

In one survey, 2.3% of patients taking labetalol HCl orally in combination with tricyclic antidepressants experienced tremor as compared to 0.7% reported to occur with labetalol HCl alone. The contribution of each of the treatments to this adverse reaction is unknown but the possibility of a drug interaction cannot be excluded.

Drugs possessing beta-blocking properties can blunt the bronchodilator effect of beta-receptor agonist drugs in patients with bronchospasm; therefore, doses greater than the normal anti-asthmatic dose of beta-agonist bronchodilator drugs may be required.

Cimetidine has been shown to increase the bioavailability of labetalol HCl administered orally. Since this could be explained either by enhanced absorption or by an alteration of hepatic metabolism of labetalol HCl, special care should be used in establishing the dose required for blood pressure control in such patients.

Synergism has been shown between halothane anesthesia and intravenously administered labetalol HCl. During controlled hypotensive anesthesia using labetalol HCl in association with halothane, high concentrations (3% or above) of halothane should not be used because the degree of hypotension will be increased and because of the possibility of a large reduction in cardiac output and an increase in central venous pressure. The anesthesiologist should be informed when a patient is receiving labetalol HCl.

Labetalol HCl blunts the reflex tachycardia produced by nitroglycerin without preventing its hypotensive effect. If labetalol HCl is used with nitroglycerin in patients with angina pectoris, additional antihypertensive effects may occur.

Drug/Laboratory Test Interactions

The presence of a metabolite of labetalol in the urine may result in falsely increased levels of urinary catecholamines when measured by a nonspecific trihydroxyindole (THI) reaction. In screening patients suspected of having a pheochromocytoma and being treated with labetalol HCl, specific radioenzymatic or high performance liquid chromatography assay techniques should be used to determine levels of catecholamines or their metabolites.

Carcinogenesis, Mutagenesis, Impairment of Fertility

Long-term oral dosing studies with labetalol HCl for 18 months in mice and for 2 years in rats showed no evidence of carcinogenesis. Studies with labetalol HCl, using dominant lethal assays in rats and mice, and exposing microorganisms according to modified Ames tests, showed no evidence of mutagenesis.

Pregnancy Category C

Teratogenic studies have been performed with labetalol in rats and rabbits at oral doses up to approximately 6 and 4 times the MRHD, respectively. No reproducible evidence of fetal malformations was observed. Increased fetal resorptions were seen in both species at doses approximating the MRHD. There are no adequate and well-controlled studies in pregnant women. Labetalol should be used during pregnancy only if the potential benefit justifies the potential risk to the fetus.

Nonteratogenic Effects

Infants of mothers who were treated with labetalol HCl for hypertension during pregnancy did not appear to be adversely affected by the drug. Oral administration of labetalol to rats during late gestation through weaning at doses of 2 to 4 times the MRHD caused a decrease in neonatal survival.

Labor and Delivery

Labetalol HCl given to pregnant women with hypertension did not appear to affect the usual course of labor and delivery.

Nursing Mothers

Small amounts of labetalol (approximately 0.004% of the maternal dose) are excreted in human milk. Caution should be exercised when TRANDATE® (labetalol HCl) Injection is administered to a nursing woman.

Pediatric Use

Safety and effectiveness in children have not been established.

ADVERSE REACTIONS

TRANDATE® (labetalol HCl) Injection is usually well tolerated. Most adverse effects have been mild and transient and in controlled trials involving 92 patients did not require labetalol HCl withdrawal. Symptomatic postural hypotension (incidence 58%) is likely to occur if patients are tilted or allowed to assume the upright position within 3 hours of receiving TRANDATE (labetalol HCl) Injection. Moderate hypotension occurred in 1 of 100 patients while supine. Increased sweating was noted in 4 of 100 patients, and flushing occurred in 1 of 100 patients.

The following also were reported with TRANDATE (labetalol HCl) Injection with the incidence per 100 patients as noted:

Cardiovascular System: Ventricular arrhythmia in 1.

Central and Peripheral Nervous Systems: Dizziness in 9; tingling of the scalp/skin 7; hypoesthesia (numbness), and vertigo 1 each.

Gastrointestinal System Nausea in 13; vomiting 4; dyspepsia and taste distortion, 1 each.

Metabolic Disorders Transient increases in blood urea nitrogen and serum creatinine levels occurred in 8 of 100 patients; these were associated with drops in blood pressure, generally in patients with prior renal insufficiency.

Psychiatric Disorders: Somnolence/yawning in 3.

Respiratory System: Wheezing in 1.

Skin: Pruritus in 1.

The incidence of adverse reactions depends upon the dose of labetalol HCl. The largest experience is with oral labetalol HCl (see TRANDATE Tablet Product Information for details). Certain of the side effects increased with increasing oral dose in the entire U.S. therapeutic trials data base for adverse reactions that are clearly or possibly dose-related.

The oculomucocutaneous syndrome associated with the beta-blocker practolol has not been reported with labetalol HCl during investigational use and extensive foreign marketing experience.

Clinical laboratory tests: Among patients dosed with TRANDATE (labetalol HCl) Tablets, there have been reversible increases of serum transaminases in 4% of patients tested, and more rarely, reversible increases in blood urea.

OVERDOSAGE

Overdosage with TRANDATE® (labetalol HCl) Injection causes excessive hypotension which is posture sensitive, and sometimes, excessive bradycardia. Patients should be laid supine and their legs raised if necessary to improve blood supply to the brain. The following additional measures should be employed if necessary: *Excessive bradycardia*—administer atropine (3.0 mg). If there is no response to vagal blockade, administer isoproterenol cautiously. *Cardiac failure*—administer a digitalis glycoside and a diuretic. *Hypotension*—administer vasopressors, e.g., norepinephrine. There is pharmacological evidence that norepinephrine may be the drug of choice. *Bronchospasm*—administer a beta$_2$-stimulating agent and/or a theophylline preparation.

If overdosage with labetalol HCl follows oral ingestion, gastric lavage or pharmacologically induced emesis (using syrup of ipecac) is useful for removal of the drug shortly after ingestion. Labetalol HCl can be removed from the general circulation by hemodialysis.

The oral LD_{50} value of labetalol HCl in the mouse is approximately 600 mg/kg and in the rat is greater than 2 gm/kg. The intravenous LD_{50} in these species is 50 to 60 mg/kg.

DOSAGE AND ADMINISTRATION

TRANDATE® (labetalol HCl) Injection is intended for intravenous use in hospitalized patients. DOSAGE MUST BE INDIVIDUALIZED depending upon the severity of hypertension and the response of the patient during dosing.

Patients should always be kept in a supine position during the period of intravenous drug administration. A substantial fall in blood pressure on standing should be expected in these patients. The patient's ability to tolerate an upright position should be established before permitting any ambulation, such as using toilet facilities.

Either of two methods of administration of TRANDATE Injection may be used: a) repeated intravenous injections, b) slow continuous infusion.

Repeated Intravenous Injection: Initially, TRANDATE (labetalol HCl) Injection should be given in a dose of 20 mg labetalol HCl (which corresponds to 0.25 mg/kg for an 80 kg patient) by slow intravenous injection over a two-minute period.

Immediately before the injection and at five and ten minutes after injection, supine blood pressure should be measured to evaluate response. Additional injections of 40 mg or 80 mg can be given at ten-minute intervals until a desired supine blood pressure is achieved or a total of 300 mg labetalol HCl has been injected. The maximum effect usually occurs within 5 minutes of each injection.

Slow Continuous Infusion: TRANDATE (labetalol HCl) Injection is prepared for intravenous continuous infusion by diluting the ampule contents with commonly used intravenous fluids (see below). Examples of two methods of preparing the infusion solution are:

The contents of two ampules (40 ml) are added to 160 ml of a commonly used intravenous fluid such that the resultant 200 ml of solution contains 200 mg of labetalol HCl, 1 mg/ml. The diluted solution should be administered at a rate of 2 ml/min to deliver 2 mg/min.

Alternatively, the contents of two ampules (40 ml) of TRANDATE (labetalol HCl) Injection can be added to 250 ml of a commonly used intravenous fluid. The resultant solution will contain 200 mg of labetalol HCl, approximately 2 mg/3 ml. The diluted solution should be administered at a rate of 3 ml/min to deliver approximately 2 mg/min.

The rate of infusion of the diluted solution may be adjusted according to the blood pressure response, at the discretion of the physician. To facilitate a desired rate of infusion, the diluted solution can be infused using a controlled administration mechanism, e.g., graduated burette or mechanically driven infusion pump.

Since the half life of labetalol is 5 to 8 hours, steady-state blood levels (in the face of a constant rate of infusion) would not be reached during the usual infusion time period. The infusion should be continued until a satisfactory response is obtained and should then be stopped and oral labetalol HCl started (see below). The effective intravenous dose is usually in the range of 50 to 200 mg. A total dose of up to 300 mg may be required in some patients.

Blood Pressure Monitoring: The blood pressure should be monitored during and after completion of the infusion or intravenous injections. Rapid or excessive falls in either systolic or diastolic blood pressure during intravenous treatment should be avoided. In patients with excessive systolic hypertension, the decrease in systolic pressure should be used as an indicator of effectiveness in addition to the response of the diastolic pressure.

Initiation of Dosing with TRANDATE (labetalol HCl) Tablets: Subsequent oral dosing with TRANDATE (labetalol HCl) Tablets should begin when it has been established that the supine diastolic blood pressure has begun to rise. The recommended initial dose is 200 mg, followed in 6-12 hours by an additional dose of 200 or 400 mg, depending on the blood pressure response. Thereafter, *inpatient titration with TRANDATE (labetalol HCl) Tablets* may proceed as follows:

Inpatient Titration Instructions

Regimen	Daily Dose*
200 mg b.i.d.	400 mg
400 mg b.i.d.	800 mg
800 mg b.i.d.	1600 mg
1200 mg b.i.d.	2400 mg

*If needed, the total daily dose may be given in three divided doses.

While in the hospital, the dosage of TRANDATE Tablets may be increased at one day intervals to achieve the desired blood pressure reduction.

For subsequent outpatient titration or maintenance dosing see TRANDATE (labetalol HCl) Tablets Product Information DOSAGE AND ADMINISTRATION for additional recommendations.

HOW SUPPLIED

TRANDATE® (labetalol HCl) Injection, 5 mg/ml, is supplied in 20 ml (100 mg) ampules, box of 1 (NDC 0173-0350-59).

Store between 2° and 30°C (36° and 86°F). Do not freeze.

Manufactured for Glaxo Inc., Research Triangle Park, NC 27709

184 Incomplete and Delayed Bioavailability of Sublingual Nitroglycerin

PATRICK K. NOONAN and LESLIE Z. BENET

Eight healthy male volunteers received 16 doses of sublingual nitroglycerin (GTN) tablets (0.4 mg). Each subject also received an i.v. GTN infusion so that the absolute bioavailability could be evaluated. The mean bioavailability (±SD) of sublingual GTN, estimated from plasma GTN concentrations, 36.2 ± 24.9% (range 2.6 to 113%). The amount of GTN not absorbed after 8 minutes, determined from the mouth rinse analyses, varied from 2.7 to 65.8% (mean 31.4 ± 18.9%) of the administered dose. A mean GTN peak concentration of 1.89 ± 1.64 ng/ml was attained. A mean peak time of 5.3 ± 2.3 minutes indicates that sublingual absorption is not instantaneous and can be relatively slow, with peak times of as long as 10 minutes. These data indicate that GTN pharmacokinetic values should not be estimated only from sublingual doses of GTN. Attempts to correlate pharmacodynamic measurements to sublingual doses must take into account the low and variable bioavailability and the potentially long peak times after sublingual GTN administration to patients.

EXPERIMENTAL STUDIES

188 Validation in Dogs of a Rapid Digital Angiographic Technique to Measure Relative Coronary Blood Flow During Routine Cardiac Catheterization

JOHN McB. HODGSON, VICTOR LeGRAND, ERIC R. BATES, G. B. JOHN MANCINI, FRED M. AUERON, WILLIAM W. O'NEILL, SANDRA B. SIMON, GLENN J. BEAUMAN, MICHAEL T. LeFREE, and ROBERT A. VOGEL

A digital angiographic technique that allows for rapid analysis of relative regional coronary blood flow using selective coronary arteriography is reported. Validation of this technique was performed in 14 instrumented dogs by comparison of digital flow ratio estimates with electromagnetic flow ratio measurements. Electrocardiographic gated digital images were acquired at baseline flow and during contrast or papaverine-induced hyperemia. Dual-parameter functional images were then generated using color and intensity coding to represent contrast medium arrival time and density, respectively. Coronary flow reserve ratios calculated digitally correlated well with actual electromagnetic flow ratios ($r = 0.92$). Digital estimates were accurate (regression slope = 0.90), reproducible (±13%) and had excellent interobserver ($r = 0.99$) and intraobserver ($r = 0.98$) variability. Thus, digital angiography can be used during routine cardiac catheterization to obtain rapid, accurate and reproducible estimates of relative regional coronary blood flow.

194 Electrophysiologic and Anatomic Changes in the Atrioventricular Junction of Dogs After Direct-Current Shocks Through Tissue Fixation Catheters

MELVIN M. SCHEINMAN, SAROJA BHARATI, YIN-SHI WANG, WILLIAM A. SHAPIRO, and MAURICE LEV

Tissue fixation electrode catheters were inserted under fluoroscopy into the region of atrioventricular (AV) node in 6 dogs and a series of shocks were delivered from the electrode catheter to a back patch. Electrophysiologic studies 2 to 3 weeks after the procedure showed only minimal changes in AV nodal conduction, whereas histologic examination showed substantial damage to the AV junction. It is concluded that there is a large safety margin for AV conduction. This technique may be applicable to patients with drug-refractory AV nodal reentrant tachycardia.

199 Mechanical "Cough" Cardiopulmonary Resuscitation During Cardiac Arrest in Dogs

JAMES T. NIEMANN, JOHN P. ROSBOROUGH, ROBERT A. NISKANEN, CLIF ALFERNESS, and J. MICHAEL CRILEY

Coughing produces systemic perfusion during ventricular fibrillation (VF). A circulatory assist apparatus was devised to reproduce the physiology of forceful coughing, i.e., simultaneous pulsatile increases in intrathoracic pressure (pneumatic vest) and intraabdominal pressure (abdominal binder). In this study, countershock outcome after 30 minutes of VF and CPR with the vest/binder device or conventional CPR are compared in 18 dogs. Aortic and right atrial (RA) pressures, the instantaneous aortic-RA difference (coronary perfusion pressure) and blood gas levels were measured. Only 1 of 9 dogs that received conventional CPR were resuscitated and survived 24 hours; 7 of 9 dogs supported with the vest/binder device were resuscitated and were neurologically normal at 24 hours ($p = 0.007$). Systolic aortic and RA pressures, mean coronary perfusion pressure, and blood gas levels were not significantly different between survivors and nonsurvivors. Peak diastolic coronary perfusion pressure averaged 23 ± 6 mm Hg for survivors, but only 6 ± 10 mm Hg for nonsurvivors ($p < 0.001$). It is concluded that (1) circulatory support techniques that use the "thoracic pump" can sustain vital organ perfusion during VF, and (2) diastolic coronary perfusion pressure is a determinant of countershock outcome and can be favorably manipulated by mechanical means.

Continued on page A56

205 **Influence of the Aortic Component of the Second Heart Sound on Left Ventricular Maximal Negative dP/dt in the Dog**

DAMON SMITH and ERNEST CRAIGE

Maximal negative left ventricular dP/dt is widely used as a measure of isovolumic muscular relaxation of the left ventricle. In the course of canine experiments designed to elucidate the hemodynamic events responsible for the aortic component of the second heart sound, high-fidelity left ventricular pressure and dP/dt signals were recorded, as well as accelerations detected on the root of the aorta and epicardium at the cardiac apex. The aortic component of the second heart sound was coincident with maximal negative dP/dt and affected its magnitude to a variable and unpredictable extent. This may account for some of the unexpected variations in magnitude of maximal negative dP/dt that have been described in various disease states as well as in laboratory experiments in which the effects of physiologic and pharmacologic interventions have been studied.

210 **Morphologic Changes Induced by Dilation of the Pulmonary Valve Anulus with Overlarge Balloons in Normal Newborn Lambs**

JOHN C. RING, THOMAS J. KULIK, BARBARA A. BURKE, and JAMES E. LOCK

The pulmonary valve anuli of 14 normal newborn lambs were dilated with angioplasty balloons 20% smaller to 90% larger than the anulus. In 3 dilations, a dynamic technique was used, consisting of withdrawal of the fully inflated balloon from the anulus into the body of the right ventricle. Twelve lambs were killed acutely, 2 were killed late, and detailed gross anatomic and microscopic observations of the heart were made. The major damage to the heart from balloon dilation is not to the pulmonary anulus, but to the right ventricular outflow tract and free wall, with mural hemorrhages of varying size. Trauma is minor if the balloon is less than 30% larger than the anulus, but is considerable when the balloon is more than 50% larger, and is worst subjacent to the proximal end of the balloon, so that longer balloons may cause greater damage. Resolution of acute right ventricular hemorrhage occurs with small, patchy areas of fibrosis.

Indications: Premature atrial and ventricular contractions, aproxysmal atrial tachycardia, paroxysmal A-V junctional rhythm, atrial flutter, paroxysmal atrial fibrillation, established atrial fibrillation when therapy is appropriate, paroxysmal ventricular tachycardia when not associated with complete heartblock, maintenance therapy after electrical conversion of atrial fibrillation and/or flutter.

Contraindications: Intraventricular conduction defects. A-V block. Idiosyncrasy or hypersensitivity.

Aberrant impulses and abnormal rhythms due to escape mechanisms should not be treated with quinidine.

Warning: In the treatment of atrial flutter, reversion to sinus rhythm may be preceded by a progressive reduction in the degree of A-V block to a 1:1 ratio and resulting in extremely rapid ventricular rate.

Precautions: All the precautions applying to regular quinidine therapy apply to the Extentab form. Use with care in patients with severe congestive failure, renal insufficiency or with digitalis intoxication.

Patients should be carefully observed for signs of toxicity: e.g., (1) allergy or idiosyncrasy, such as febrile reactions, skin eruptions, and thrombocytopenia (extremely rare); (2) "cinchonism," such as tinnitus, blurred vision, dizziness, light-headedness, and tremor; (3) G.I. symptoms (nausea, vomiting, diarrhea, and colic); (4) cardiotoxic effects such as ventricular extrasystoles occurring at the rate of one or more every 6 normal beats, an increase of the QRS complex of 50% or more, a complete A-V block, or ventricular tachycardia.

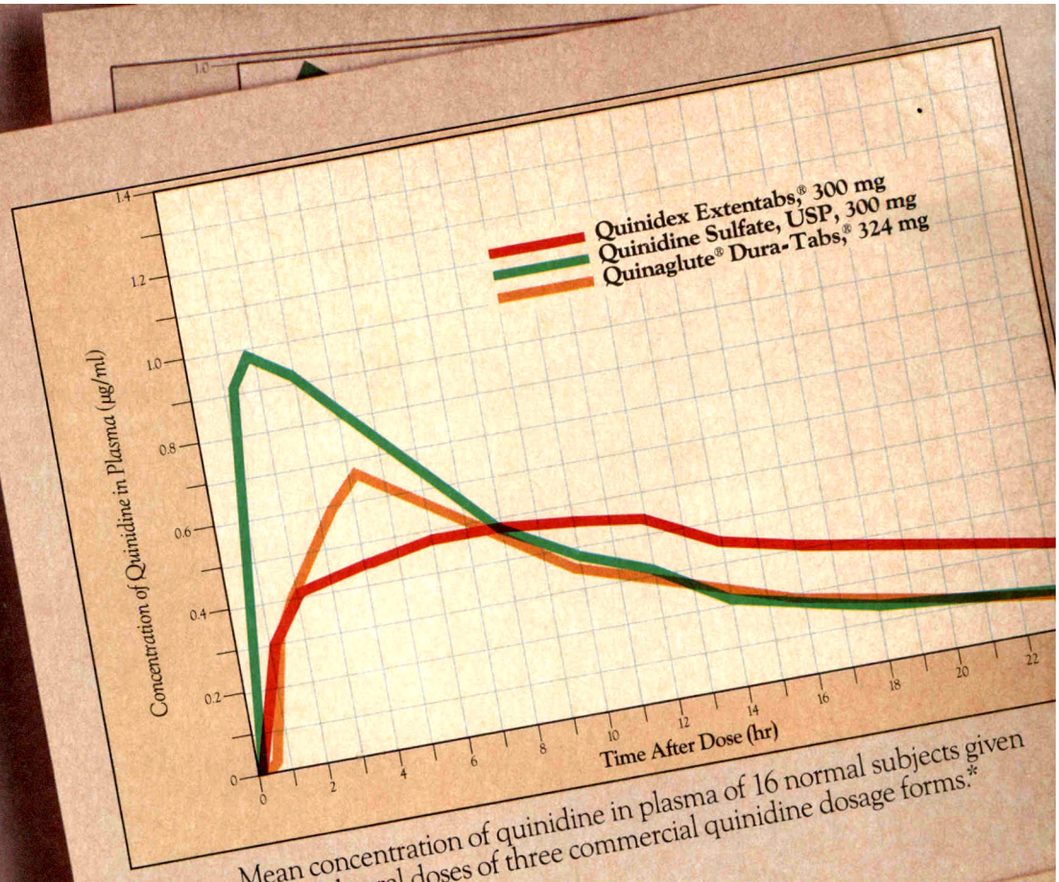
NOTE: The development of "cinchonism" is not usually sufficient reason for terminating quinidine therapy. G.I. symptoms can also be minimized by giving the drug with food.

Adverse Reactions: Cases of quinidine-induced hypoprothrombinemic hemorrhage in patients on chronic anticoagulant drug therapy have been reported.

Dosage: Two Quinidex Extentabs every 8 to 12 hours.

How Supplied: White sugar-coated Extentabs in bottles of 100 (NDC 0031-6649-63) and 250 (NDC 0031-6649-67) and Dis-co® Unit Dose Packs of 100 (NDC 0031-6649-64).

Rev. Dec. 1981



Mean concentration of quinidine in plasma of 16 normal subjects given single oral doses of three commercial quinidine dosage forms.*

Consider The Evidence For Quinidex (Quinidine Sulfate, USP), 300 mg Extentabs®

- The convenience of b.i.d. dosage*
- Up to 12 hours of smooth, sustained release
- Relative bioavailability equal to Quinidine Sulfate Tablets, USP
- Contains 48 mg more active quinidine than the leading gluconate product

*Some patients may require a t.i.d. dosage schedule.

...and protecting healing hearts in the months ahead

The combination of early intravenous administration of Lopressor followed by long-term oral therapy resulted in a 36% reduction of three-month mortality in patients with definite or suspected acute MI in the Göteborg Trial.[1]

Treatment should be continued for 1-3 years.

Lopressor is contraindicated in patients with a heart rate <45 beats/min; significant heart block greater than first degree (P-R interval ≥0.24 sec); systolic blood pressure <100 mmHg; or moderate-to-severe cardiac failure. Please see last page for Brief Summary of Prescribing Information.

...and protecting healing hearts in the months ahead

Lopressor®
metoprolol tartrate **Tablets Ampuls**

BRIEF SUMMARY
(FOR FULL PRESCRIBING INFORMATION, SEE PACKAGE INSERT)

INDICATIONS AND USAGE
Myocardial Infarction
Lopressor ampuls and tablets are indicated in the treatment of hemodynamically stable patients with definite or suspected acute myocardial infarction to reduce cardiovascular mortality. Treatment with intravenous Lopressor can be initiated as soon as the patient's clinical condition allows (see **DOSAGE AND ADMINISTRATION, CONTRAINDICATIONS,** and **WARNINGS**). Alternatively, treatment can begin within 3 to 10 days of the acute event (see **DOSAGE AND ADMINISTRATION**).

CONTRAINDICATIONS
Myocardial Infarction
Lopressor is contraindicated in patients with a heart rate < 45 beats/min; significant heart block greater than first degree (P-R interval ≥ 0.24 sec); systolic blood pressure < 100 mmHg; or moderate-to-severe cardiac failure (see **WARNINGS**).

WARNINGS
Myocardial Infarction
Cardiac Failure: Sympathetic stimulation is a vital component supporting circulatory function, and beta blockade carries the potential hazard of depressing myocardial contractility and precipitating or exacerbating minimal cardiac failure.

During treatment with Lopressor, the hemodynamic status of the patient should be carefully monitored. If heart failure occurs or persists despite appropriate treatment, Lopressor should be discontinued.

Bradycardia: Lopressor produces a decrease in sinus heart rate in most patients; this decrease is greatest among patients with high initial heart rates and least among patients with low initial heart rates. Acute myocardial infarction (particularly inferior infarction) may in itself produce significant lowering of the sinus rate. If the sinus rate decreases to < 40 beats/min, particularly if associated with evidence of lowered cardiac output, atropine (0.25-0.5 mg) should be administered intravenously. If treatment with atropine is not successful, Lopressor should be discontinued, and cautious administration of isoproterenol or installation of a cardiac pacemaker should be considered.

AV Block: Lopressor slows AV conduction and may produce significant first-(P-R interval ≥0.26 sec), second-, or third-degree heart block. Acute myocardial infarction also produces heart block.

If heart block occurs, Lopressor should be discontinued and atropine (0.25-0.5 mg) should be administered intravenously. If treatment with atropine is not successful, cautious administration of isoproterenol or installation of a cardiac pacemaker should be considered.

Hypotension: If hypotension (systolic blood pressure ≤ 90 mmHg) occurs, Lopressor should be discontinued, and the hemodynamic status of the patient and the extent of myocardial damage carefully assessed. Invasive monitoring of central venous, pulmonary capillary wedge, and arterial pressures may be required. Appropriate therapy with fluids, positive inotropic agents, balloon counterpulsation, or other treatment modalities should be instituted. If hypotension is associated with sinus bradycardia or AV block, treatment should be directed at reversing these (see above).

Bronchospastic Diseases: **PATIENTS WITH BRONCHOSPASTIC DISEASES SHOULD, IN GENERAL, NOT RECEIVE BETA BLOCKERS. Because of its relative $beta_1$ selectivity, Lopressor may be used with extreme caution in patients with bronchospastic disease. Because it is unknown to what extent $beta_2$-stimulating agents may exacerbate myocardial ischemia and the extent of infarction, these agents should *not* be used prophylactically. If bronchospasm not related to congestive heart failure occurs, Lopressor should be discontinued. A theophylline derivative or a $beta_2$ agonist may be administered cautiously, depending on the clinical condition of the patient. Both theophylline derivatives and $beta_2$ agonists may produce serious cardiac arrhythmias.**

PRECAUTIONS
General
Lopressor should be used with caution in patients with impaired hepatic function.
Information for Patients
Patients should be advised to take Lopressor regularly and continuously, as directed, with or immediately following meals. If a dose should be missed, the patient should take only the next scheduled dose (without doubling it). Patients should not discontinue Lopressor without consulting the physician.

Patients should know how they react to this medicine before they operate automobiles and machinery or engage in other tasks requiring alertness. Patients should contact the physician if any difficulty in breathing occurs, and before surgery of any type, the patient should inform the physician or dentist that he or she is taking Lopressor.
Laboratory Tests
Clinical laboratory findings may include elevated levels of serum transaminase, alkaline phosphatase, and lactate dehydrogenase.
Drug Interactions
Catecholamine-depleting drugs (e.g., reserpine) may have an additive effect when given with beta-blocking agents. Patients treated with Lopressor plus a catecholamine depletor should therefore be closely observed for evidence of hypotension or marked bradycardia, which may produce vertigo, syncope, or postural hypotension.
Carcinogenesis, Mutagenesis, Impairment of Fertility
Long-term studies in animals have been conducted to evaluate toxic effects and carcinogenic potential. In a 1-year study in dogs, there was no evidence of drug-induced toxicity at or below oral dosages of 105 mg/kg per day. In 2-year studies in rats at three oral dosage levels of up to 800 mg/kg per day, there was no increase in the development of spontaneously occurring benign or malignant neoplasms of any type. The only histologic changes that appeared to be drug-related were an increased incidence of generally mild focal accumulation of foamy macrophages in pulmonary alveoli and a slight increase in biliary hyperplasia. Neither finding represents symptoms of a known disease entity in man. In a 21-month study in mice at three oral dosage levels of up to 750 mg/kg per day, benign lung tumors (small adenomas) occurred more frequently in female mice receiving the highest dose than in untreated control animals. There was no increase in malignant or total (benign plus malignant) lung tumors, nor in the overall incidence of tumors or malignant tumors. This 21-month study was repeated, and no statistically or biologically significant differences were observed between treated and control mice of either sex for any type of tumor.
Pregnancy Category B
Reproduction studies have been performed in rats at doses up to 55.5 times the maximum daily human dose of 450 mg and have revealed no evidence of impaired fertility or teratogenicity due to Lopressor. Increased postimplantation loss and decreased neonatal survival did occur in the rats (threshold between 50 and 500 mg/kg), and distribution studies in mice confirm exposure of the fetus when Lopressor is administered to the pregnant animal. There are no adequate and well-controlled studies in pregnant women. Because animal reproduction studies are not always predictive of human response, this drug should be used during pregnancy only if clearly needed.
Nursing Mothers
Lopressor is excreted in breast milk in very small quantity. An infant consuming 1 liter of breast milk daily would receive a dose of less than 1 mg of the drug. Caution should be exercised when Lopressor is administered to a nursing woman.
Pediatric Use
Safety and effectiveness in children have not been established.

ADVERSE REACTIONS
Myocardial Infarction
Central Nervous System: Tiredness has been reported in about 1 of 100 patients. Vertigo, sleep disturbances, hallucinations, headache, dizziness, visual disturbances, confusion, and reduced libido have also been reported, but a drug relationship is not clear.

Cardiovascular: In the randomized comparison of Lopressor and placebo described in the **CLINICAL PHARMACOLOGY** section, the following adverse reactions were reported:

	Lopressor	*Placebo*
Hypotension (systolic BP < 90 mmHg)	27.4%	23.2%
Bradycardia (heart rate < 40 beats/min)	15.9%	6.7%
Second- or third-degree heart block	4.7%	4.7%
First-degree heart block (P-R ≥ 0.26 sec)	5.3%	1.9%
Heart failure	27.5%	29.6%

Respiratory: Dyspnea of pulmonary origin has been reported in fewer than 1 of 100 patients.

Gastrointestinal: Nausea and abdominal pain have been reported in fewer than 1 of 100 patients.

Dermatologic: Rash and worsened psoriasis have been reported, but a drug relationship is not clear.

Miscellaneous: Unstable diabetes and claudication have been reported, but a drug relationship is not clear.
Potential Adverse Reactions
A variety of adverse reactions not listed above have been reported with other beta-adrenergic blocking agents and should be considered potential adverse reactions to Lopressor.

Central Nervous System: Reversible mental depression progressing to catatonia; an acute reversible syndrome characterized by disorientation for time and place, short-term memory loss, emotional lability, slightly clouded sensorium, and decreased performance on neuropsychometrics.

Cardiovascular: Intensification of AV block (see **CONTRAINDICATIONS**).

Hematologic: Agranulocytosis, nonthrombocytopenic purpura, thrombocytopenic purpura.

Hypersensitive Reactions: Fever combined with aching and sore throat, laryngospasm, and respiratory distress.

DOSAGE AND ADMINISTRATION
Myocardial Infarction
Early Treatment: During the early phase of definite or suspected acute myocardial infarction, treatment with Lopressor can be initiated as soon as possible after the patient's arrival in the hospital. Such treatment should be initiated in a coronary care or similar unit immediately after the patient's hemodynamic condition has stabilized.

Treatment in this early phase should begin with the intravenous administration of three bolus injections of 5 mg of Lopressor each; the injections should be given at approximately 2-minute intervals. During the intravenous administration of Lopressor, blood pressure, heart rate, and electrocardiogram should be carefully monitored.

In patients who tolerate the full intravenous dose (15 mg), Lopressor tablets, 50 mg every 6 hours, should be initiated 15 minutes after the last intravenous dose and continued for 48 hours. Thereafter, patients should receive a maintenance dosage of 100 mg twice daily (see ***Late Treatment*** below).

Patients who appear not to tolerate the full intravenous dose should be started on either 25 mg or 50 mg every 6 hours (depending on the degree of intolerance) 15 minutes after the last intravenous dose or as soon as their clinical condition allows. In patients with severe intolerance, treatment with Lopressor should be discontinued (see **WARNINGS**).

Late Treatment: Patients with contraindications to treatment during the early phase of suspected or definite myocardial infarction, patients who appear not to tolerate the full early treatment, and patients in whom the physician wishes to delay therapy for any other reason should be started on Lopressor tablets, 100 mg twice daily, as soon as their clinical condition allows. Therapy should be continued for at least 3 months. Although the efficacy of Lopressor beyond 3 months has not been conclusively established, data from studies with other beta blockers suggest that treatment should be continued for 1-3 years.

Note: **Parenteral drug products should be inspected visually for particulate matter and discoloration prior to administration, whenever solution and container permit.**

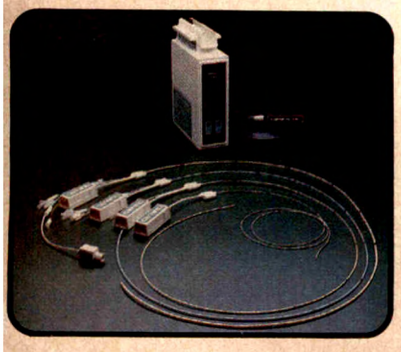
THE ULTIMATE PRESSURE MONITORING SYSTEM IS AT YOUR FINGERTIPS



You're looking at the first transducer small enough to fit in a catheter, and economical enough to be disposable.

The Camino system contains the latest developments in fiber optics, metallurgy, and microprocessors. All in a 5 French catheter.

Now you can routinely measure hemodynamic pressures right at the source. No more fluid-filled tubes to degrade the pressure waves or produce artifacts. No more external transducers to buy or calibrate. The result is unsurpassed fidelity and convenience.

For more information, write Camino Laboratories.

• Camino System 420 includes digital pressure monitor and choice of transducer-catheters.

The Diagnosis and Treatment Oriented Approach to Rheumatology with the Primary Care Physician in Mind

Rheumatology

A Primary Care Approach

Written by:

Bruce M. Rothschild, MD

Director, Division of Rheumatology, University Health Sciences, The Chicago Medical School Chief, Section of Rheumatology, V.A. Medical Center North Chicago, Illinois

ISBN 0-914316-33-8, $42.50, 430 pp., illus., 1982.

What is Rheumatology: A Primary Care Approach?

- a succinct (approx. 450 pp.) yet comprehensive presentation of the latest techniques in diagnosis and therapeutic interventions of most use to the primary care physician
- a practical "how-to" desk reference to a difficult but common disease affecting over 35 million patients in the U.S. alone
- a book meant to be used regularly, not read once and stored away on a library shelf
- the primary care physicians' answer to the huge, weighty tomes on Rheumatology which offer too little on diagnosis and treatment and too much on etiology and mechanisms of disease

Abbreviated Table of Contents

Section 1 **Investigative Techniques**
Section 2 **Patterns**
Section 3 **Management**

"This compact, well-designed and generally informative volume is a useful reference for the management of rheumatic disease by physicians who deliver primary care. The family physician will undoubtedly use this frequently as a reference."
Charles M. Plotz, MD American Family Physician

"This book is a good primer for students, residents, and health professionals who would like a glimpse into rheumatology. It can be recommended for all but the specialist (but perhaps the specialist should read it, too, to see what those he is training are learning)."
George E. Ehrlich, MD JAMA September '83

This is a superb text by a sensitive, concerned, organized author of international repute . . . Each chapter is well outlined, concise, practical, and has a current and appropriate bibliography at the end . . . a skillfully structured text which is a quality contribution . . . a very readable text."
John A. Feagin, Jr., MD Military Medicine March '83

NITROSTAT®
(nitroglycerin tablets, USP)

Before prescribing, please see full prescribing information.
A Brief Summary follows:

INDICATIONS
Nitroglycerin is indicated for the prophylaxis, treatment and management of patients with angina pectoris.

CONTRAINDICATIONS
Sublingual nitroglycerin therapy is contraindicated in patients with early myocardial infarction, severe anemia, increased intracranial pressure, and those with a known hypersensitivity to nitroglycerin.

PRECAUTIONS
Only the smallest dose required for effective relief of the acute anginal attack should be used. Excessive use may lead to the development of tolerance. Nitrostat tablets are intended for sublingual or buccal administration and should not be swallowed. The drug should be discontinued if blurring of vision or drying of the mouth occurs. Excessive dosage of nitroglycerin may produce severe headaches.

ADVERSE REACTIONS
Transient headache may occur immediately after use. Vertigo, weakness, palpitation, and other manifestations of postural hypotension may develop occasionally, particularly in erect, immobile patients. Syncope due to nitrate vasodilation has been reported. Alcohol may accentuate the cerebral ischemia symptoms.

METHOD OF ADMINISTRATION
One tablet should be dissolved under the tongue or in the buccal pouch at the first sign of an acute anginal attack. The dose may be repeated approximately every five minutes until relief is obtained. Nitrostat may be used prophylactically five to ten minutes prior to engaging in activities which might precipitate an acute attack.

HOW SUPPLIED
Nitrostat is supplied in four strengths in bottles containing 100 tablets each, with color-coded labels, and in color-coded Patient Convenience Packages of four bottles of 25 tablets each.

0.15 mg (1/400 grain):
N 0071-0568-24—Bottle of 100 tablets;
N 0071-0568-13—Convenience Package.

0.3 mg (1/200 grain):
N 0071-0569-24—Bottle of 100 tablets;
N 0071-0569-13—Convenience Package.

0.4 mg (1/150 grain):
N 0071-0570-24—Bottle of 100 tablets;
N 0071-0570-13—Convenience Package.

0.6 mg (1/100 grain):
N 0071-0571-24—Bottle of 100 tablets;
N 0071-0571-13—Convenience Package.

NATURE
HAS A WAY
OF PROTECTING
ITS OWN.

So does NITROSTAT®
(nitroglycerin tablets, USP)

Just by the way it's made, NITROSTAT, too, has built-in protection—protection against loss of nitroglycerin. In fact, NITROSTAT is more stable than conventional nitroglycerin tablets under all conditions of temperature and humidity tested.

But that's not all. Average assay still shows better than 100% of labe claim for at least 60 months after manufacture of NITROSTAT. Because of this stability NITROSTAT has a five-year expiration date.*

What's more, only NITROSTAT Tablets are available in convenient packages of 4 x 25 tablets. So emergency angina relief can be ready when needed in four different locations. "Because of its rapid action, long-established efficacy, and low cost, nitroglycerin is the most useful drug among the organic nitrates that can be given sublingually."[1] NITROSTAT... useful alone or as concomitant therapy with long-acting nitrates or propranolol.

*Five-year expiration date when stored at recommended storage conditions in an unopened bottle. Data on file, Medical Affairs Dept, Parke-Davis.

CORONARY HEART DISEASE

Baseline Rest Electrocardiographic Abnormalities, Antihypertensive Treatment, and Mortality in the Multiple Risk Factor Intervention Trial

MULTIPLE RISK FACTOR INTERVENTION TRIAL RESEARCH GROUP

The overall results of the Multiple Risk Factor Intervention Trial (MRFIT) showed a nonsignificant 7% lower coronary artery disease (CAD) mortality rate in the special-intervention (SI) as compared to the usual-care (UC) group. The initial results also suggested that the SI program was more effective than UC in the community in reducing the CAD mortality rate in nonhypertensive persons than in hypertensive persons, and that the SI program used was more effective in reducing CAD deaths among men without than men with electrocardiographic (ECG) abnormalities at rest. Furthermore, an unfavorable mortality trend in hypertensive SI men with ECG abnormalities at rest compared with UC men was noted (adjusted relative risk of 1.67). Further analyses in baseline-defined subgroups indicated that (1) the most common ECG abnormalities at rest were high R waves and ST-T changes, (2) the CAD mortality differential (SI/UC) was similar in the subgroup with these abnormalities and in the subgroup with other abnormalities at rest, (3) the apparent excess CAD mortality among hypertensive SI men with ECG abnormalities at rest was manifested chiefly as sudden death within 1 hour, and (4) the association between ECG abnormalities at rest and the CAD mortality rate among hypertensive men was independent of the baseline level of blood pressure or of the findings on the exercise electrocardiogram. However, CAD mortality in those with abnormalities on the electrocardiogram both at rest and during exercise was lower in the SI than the UC group.

A possible explanation for the difference in outcome in the baseline-defined subgroup was an unexpectedly low UC mortality rate. However, within-group analysis revealed an interaction between ECG abnormalities at rest and diuretic treatment in the SI group, with the risk of CAD death for men prescribed diuretic drugs relative to men not prescribed diuretic drugs estimated as 3.34 among men with baseline ECG abnormalities at rest and as 0.95 among men without such abnormalities. No such effect was found in the UC group, in which men generally were prescribed lower doses of hydrochlorothiazide and chlorthalidone than SI men. However, analyses do not suggest an effect of diuretic dose or of hypokalemia on the CAD mortality rate in treated SI participants. Although subgroup analyses must be interpreted with caution, particularly those that go beyond the randomized clinical trial design by the MRFIT, these findings pose hypotheses for investigation by other researchers in systemic hypertension and may have implications for therapy. **(Am J Cardiol 1985;55:1–15)**

The participating investigators and their institutional affiliations are listed in the Appendix. Manuscript received June 15, 1984; revised manuscript received September 10, 1984, accepted September 11, 1984.

Address for reprints: Marcus O. Kjelsberg, PhD, Biometry Division, School of Public Health, University of Minnesota, Suite 508, 2829 University Avenue Southeast, Minneapolis, Minnesota 55414.

The Multiple Risk Factor Intervention Trial (MRFIT) was a randomized primary prevention trial that tested the effect of a multifactor intervention program on mortality from coronary artery disease (CAD) in 12,866 men aged 35 to 57 years, selected on the basis of elevated

serum cholesterol level, or high diastolic blood pressure (BP), or cigarette smoking, or a combination of these factors. The previously reported mortality results of the MRFIT showed a nonsignificant 7% lower CAD mortality rate in the special-intervention (SI) compared with the usual-care (UC) group.[1] An explanation for these findings—that risk factor reduction is simply ineffective—was noted as unlikely in the initial report, given the weight of findings from other studies. Two other explanations are plausible.

First, the CAD and total death rates were considerably lower than had been anticipated in both SI and UC participants. This reduced the power to test the principal hypothesis; thus, the confidence interval about the CAD mortality difference ranged from 25% benefit to 15% harm (approximate 90% limits). The inconclusive result may therefore represent a type II error—a false-negative finding due to chance. The second plausible explanation was that the mortality comparison between all SI and UC participants represented an average of differential responses in important subgroups. For example, there were 35 SI and 45 UC deaths from CAD among men who were not hypertensive at baseline, whereas there were 80 SI and 79 UC CAD deaths among those who were hypertensive.[1] Within the hypertensive subgroup, SI death rates from CAD and all causes were lower than UC death rates for men free of baseline electrocardiographic (ECG) abnormalities at rest. However, hypertensive SI participants with baseline ECG abnormalities at rest had more CAD deaths than their UC counterparts. Furthermore, and in contrast, SI participants with ECG abnormalities during exercise at entry had a significant 57% lower CAD mortality rate than the similar group of UC participants.[2] These findings support the interpretation that the MRFIT total experience represents the sum of substantially different findings in various subgroups.

In this article the CAD mortality findings for nonhypertensive and hypertensive men with and without ECG abnormalities at rest are examined further. In addition, the association between diuretic use and CAD mortality is studied and possible mechanisms are considered.

Design and Methods

Design: The design of the MRFIT has been described.[1,3,4] Briefly, male volunteers, mostly from employee groups, were recruited in 18 U.S. cities. They were screened to select those in the upper 15% (later changed to 10%) of a risk-score distribution derived from Framingham data, with the score a function of serum cholesterol concentration, cigarette smoking and diastolic BP. Those free of overt CAD by history and electrocardiogram at rest otherwise suitable for a long-term trial, and agreeable to being randomized, were assigned in essentially equal numbers to SI and UC groups. SI men participated in an intensive program aimed at lowering blood cholesterol levels by nutritional means, eliminating cigarette smoking through education and behavior modification techniques, and reducing diastolic BP of hypertensive men primarily using a stepped-care drug regimen. UC participants were referred to their customary source of medical care along with information on risk factor status, but were given no advice as to intervention. Both groups were examined annually over 6 to 8 years for determination of risk factors and morbid endpoints. CAD mortality was the primary endpoint; ascertainment of vital status at the end of follow-up in February 1982 was 99.7% complete, and a cause of death was assigned in all but 3% of deaths.[1]

Before termination of the trial and access to endpoint data, the MRFIT Steering Committee formulated 2 subgroup hypotheses related to baseline ECG abnormalities at rest and to ECG response to a heart-rate-limited exercise test, respectively. One postulated that among men without baseline ECG abnormalities at rest, the SI group would have a lower CAD mortality than the UC group. Similarly, the other postulated a corresponding difference in participants with a normal electrocardiogram during exercise. It was presumed that men in each subgroup had less advanced cardiac involvement and therefore would be more responsive to the intervention effort than men who had ECG abnormalities. Because men without ECG abnormalities made up the great majority of the MRFIT cohort, there was judged to be reasonable power to test these postulates. Neither hypothesis incorporated any relation to hypertension or antihypertensive treatment. However, prior analysis plans called for assessing endpoint data for specific subgroups, e.g., those hypertensive at baseline, to determine whether MRFIT findings were consistent with those of the Hypertension Detection and Follow-up Program.[5] The number of men with hypertension at baseline was not, however, large enough to warrant formulating a specific and formal hypothesis.

Baseline and follow-up measurements: BP was measured on 3 occasions before randomization. At initial screening, BP was measured 3 times to determine, along with number of cigarettes smoked per day and total serum cholesterol, if the man met risk eligibility criteria. Four additional BP measurements with the man seated after a 5-minute rest were made at both second and third screening visits. Baseline BP was defined as the average of the 2 random-0 manometer readings at second screening and the 2 random-0 readings at third screening. A participant was considered hypertensive at entry if his baseline diastolic BP was 90 mm Hg or higher, or if he reported that he was currently taking antihypertensive drugs at the second screening. Follow-up diastolic BP recorded at annual visits was similarly measured and defined (average of 2 random-0 readings).

Electrocardiograms at rest were performed at the second screening and read at the local clinics to exclude from the study men with evidence of a previous myocardial infarction, major atrioventricular conduction defect, complete bundle branch block, or arrhythmia that required treatment.* Another electrocardiogram at rest was recorded at third screening, and was read according to the Minnesota code[6] both visually at the ECG Coding Center (University of Minnesota) and by computer algorithm at the Computer ECG Center (Dalhousie University).*

Because of the performance of an exercise test at the third screening, modified limb electrode positions were used to record the standard 12-lead electrocardiogram at this visit. The modified lead placements have been described.[2] Because of the torso placement of the limb electrodes, R-wave abnormalities were coded at baseline using chest leads only.[7†]

* Resting ECG exclusion criteria (Minnesota codes) were as follows: at second screening, 1.1, 1.2 plus 5.1 or 5.2, 6.1, 6.2, 6.2.2, 6.4, 7.1.1, 7.2.1, 7.4 plus 5.1 or 5.2, 8.2.2, 8.3, any paroxysmal tachyarrhythmia; at third screening, 1.1, 1.2 plus 5.1 or 5.2.

† An exception to this coding rule was made for 1 clinical center where the electrocardiograms initially produced a false calibration. When the recalibrated tracings were read during the middle of the trial, R-wave abnormalities were coded using both chest and modified limb leads.

Since the computer identified approximately 34% more participants with ECG abnormalities at rest than did the visual coding, key analyses were performed based on both the computer and visually determined Minnesota codes. The associations identified using the visually coded data were not substantially altered by use of the computer coding. The data from electrocardiograms at rest presented in this report were derived from the visual readings only, for consistency with the earlier report on mortality findings.[1]

An electrocardiogram during exercise was also performed at the third screening, and its detailed findings are the subject of a separate paper.[2] Briefly, participants exercised on a treadmill with stepwise increase of slope and speed until a predetermined heart rate was reached, or to an earlier termination for specified reasons. An abnormal exercise test was defined based on the computer classification of ST-segment depression, measured as the area between this segment and the isoelectric line. The criteria were as follows: an ST-depression integral of at least 16 μV-s at peak exercise or in the immediate or 3-minute recovery record in any of the leads CS_5, aVL, aVF or V_5, with the ST-depression integral in the preexercise sitting record less than 6 μV-s in all of these leads.

Blood chemistry determinations at screening and annual visits included serum or plasma levels of cholesterol, triglycerides, lipoproteins, thiocyanate, and potassium, and were performed using methods previously described.[8,9]

Intervention on blood pressure: A goal BP was established if an SI participant reported having antihypertensive medication prescribed for him by his personal physician (regardless of BP level), or if an untreated man was found to have a diastolic BP of 90 mm Hg or higher on 2 consecutive monthly visits, beginning with and including the third screening visit. The reading at the second of these visits was used to establish the treatment goal: either 89 mm Hg or a reduction of 10 mm Hg, whichever was lower, but not less than 80 mm Hg. Men who had a diastolic BP of 90 mm Hg or less and who were already taking antihypertensive drugs prescribed by a personal physician were assigned a goal of 80 mm Hg. Before drug prescription, weight reduction was attempted for overweight men. Drugs were prescribed according to a stepped-care protocol beginning with 50 mg of either hydrochlorothiazide or chlorthalidone, at the discretion of the clinic physician, up to a maximal dose of 100 mg/day.

In 1979, during the fourth to fifth year of follow-up, data suggesting an adverse response to the BP intervention were noted by the Coordinating Center and reported to the Policy Advisory Board. Based on these findings, and in light of the then recently reported successful outcome of the Hypertension Detection and Follow-up Program, in which chlorthalidone has been used as the main diuretic drug,[5] it was decided that all clinics should change therapy from hydrochlorothiazide to chlorthalidone as the diuretic of choice. Because it had become widely recognized that a smaller dose of diuretic usually resulted in BP lowering similar to that of a larger dose,[10] clinics were advised to switch SI participants prescribed hydrochlorothiazide to 50 mg of chlorthalidone irrespective of the currently prescribed dosage of hydrochlorothiazide. These changes in the protocol were largely implemented between March and June, 1980. The data related to this change will be described in greater detail in another report.

Further details of the MRFIT stepped-care protocol, including step II, III and IV drugs, have been published.[1,11] SI men were seen at least every 4 months; those assigned a goal BP were seen more often until goal was reached. Serum levels of potassium were determined and reported centrally every 4 months.

The decisions on when and how to treat UC participants for hypertension were made by their own physicians. These men were seen yearly at MRFIT clinics, at which time they were questioned about current medications and requested to bring these to the examination. Their personal physicians received reports, including BP measurements, of each annual MRFIT examination.

Determination of endpoints: Methods of mortality ascertainment have been reported.[1] Classification of cause of death was performed by a committee of 3 cardiologists not affiliated with MRFIT in any other respect. They used hospital records, physicians' reports, next-of-kin interviews, death certificates and autopsy reports (in about one-third of deaths in each group). Group assignment was carefully masked. CAD deaths were subclassified as (1) documented myocardial infarction; (2) sudden death within 60 minutes, or between 1 and 24 hours of symptom onset, without documented myocardial infarction; (3) congestive heart failure due to CAD; or (4) death associated with surgery for CAD.

Statistical methods: Mortality results are presented in life-table functions using the Kaplan-Meier product limit method.[12] Comparisons of mortality for baseline defined subgroups were summarized using the log-rank test.[13] Heterogeneity of relative risks (SI/UC) for baseline defined subgroups was evaluated using the Cox proportional hazards model[14] with Breslow's approximation.[15] Interaction terms were defined that involved an indicator variable for study group (SI or UC) and the other factor under study, e.g., the presence or absence of ECG abnormalities at rest or baseline hypertensive status. The significance of the interaction with study group was evaluated by considering the maximized log likelihood for the model with and without the interaction term.

A test for the linear trend of relative risk estimates was performed using weighted least squares. The log odds ratio for each stratum was regressed on the midpoint of the stratum. Weights were chosen as the inverse of the variance of the log odds ratio.

Univariate comparisons of the relation to mortality of variables related to treatment of hypertension were made using person-years analyses. In these analyses length of exposure in days to the factor under study, e.g., treatment status (no diuretic, diuretic), was tabulated and summed across individual participants and periods of follow-up. The exposure period was approximated using data on current status reported at annual visits.

The Cox proportional hazards model adapted for use with time-dependent covariates was used to investigate the association of characteristics of the hypertension intervention program and subsequent CAD death. In these analyses covariates for age, the initial levels of diastolic BP, serum cholesterol and cigarette smoking, change in serum cholesterol, change in diastolic BP (in some models), and an indicator variable for thiocyanate-confirmed smoking cessation were included in the regression model, as well as indicator variables to denote diuretic prescription, the presence or absence of ECG abnormalities at rest, and the interaction of ECG abnormalities at rest with diuretic use. The characteristics under study were updated annually through 7 years, and missing observations were assigned the value from the last attended annual follow-up visit. The statistical significance of the regression coefficient corresponding to the interaction of diuretic use and baseline ECG abnormalities at rest was determined by examining the increase in the maximized log likelihood compared with the model that did not allow for an interaction.

MRFIT was not designed to estimate effects of individual intervention, i.e., a factorial arrangement of the intervention was not used. Therefore, much of this investigation involved the use of a statistical model to adjust for possible influences of various risk factors on outcome. For example, unadjusted SI-UC comparisons of hypertensive and nonhypertensive

subjects at entry implicitly assume that the degrees of smoking and dietary intervention were similar for SI hypertensive and nonhypertensive subjects. This was unlikely, since the trial selection criteria resulted in higher serum cholesterol levels and more cigarette smoking for nonhypertensive men than hypertensive men at entry and, consequently, possible differential intervention in these areas during follow-up. Multivariate analyses were used to attempt to control for these differences, but results of such analyses can be influenced by the particular set of covariates used. By definition, comparisons of baseline-defined subgroups do not take into account the actual interventions used and risk factor changes achieved. To go beyond this limitation, within-group analyses of subgroups defined by factors determined after randomization were performed. For such within-group analyses, inferences are limited, because of the lack of a randomized control group.

Significance probabilities (p values) are unadjusted for multiple comparisons and thus those cited should be viewed only as guidelines. In accordance with usual standards, 2-sided p values <0.05 are termed nominally significant.

Results

Coronary artery disease mortality rate in baseline-defined subgroups (special-intervention vs usual-care): As of February 28, 1982, after an average period of follow-up of 7 years, there were 88 CAD deaths among UC men (18.8 per 1,000) without ECG abnormalities at rest and 68 CAD deaths among SI men (14.8 per 1,000) without ECG abnormalities at rest. The life table Z value of −1.54 (p = 0.12) for men without ECG abnormalities at rest gives some support to the hypothesis that the SI men would have a lower CAD mortality rate than the UC group in this subgroup, but the observed difference could also well be due to chance. For men with ECG abnormalities at rest, SI participants had a higher CAD mortality rate than UC men (47 SI CAD deaths compared to 36 UC deaths), but again the difference is not statistically significant (Z = 1.09, p = 0.28). The difference in the relative risk of CAD death (SI/UC) for men with (1.26) and without (0.79) ECG abnormalities at rest is large but nonsignificant (nominal p = 0.08). This difference suggests some heterogeneity of outcome and attenuation of benefit of risk factor intervention for men with ECG abnormalities at rest.

Because the intervention itself could have differed according to ECG findings at baseline, risk factor levels and use of antihypertensive treatment at 48 months, a point somewhat more than halfway through the study, are compared for SI and UC men with and without ECG abnormalities at rest (Table I). The SI-UC differences in risk factor levels and in the use of antihypertensive drugs are similar for the 2 subgroups defined by the presence/absence of baseline ECG abnormalities at rest. Therefore, it seems unlikely that the apparent difference noted in relative risk (SI/UC) of CAD death for men with and without ECG abnormalities at rest arises from differential degrees of intervention, relative to UC changes, for the 2 subgroups.

This apparent difference in relative risks was investigated further to determine whether any components of the intervention were associated with a decreased benefit. Initial evidence[1] indicated that the differential effectiveness of the intervention according to the presence of baseline ECG abnormalities at rest was associated with baseline hypertensive status. This finding is illustrated by adjusted relative risk (SI/UC) estimates for dichotomized levels of the risk factors at baseline (Table II). For men without ECG abnormalities at rest, no substantial differences were noted in the relative risk estimates by level of the risk factors. In the presence of ECG abnormalities at rest, there were also only minimal differences for strata defined by smoking status and level of serum cholesterol. However, the difference in relative risks between hypertensive and nonhypertensive subgroups are larger and on opposite sides of

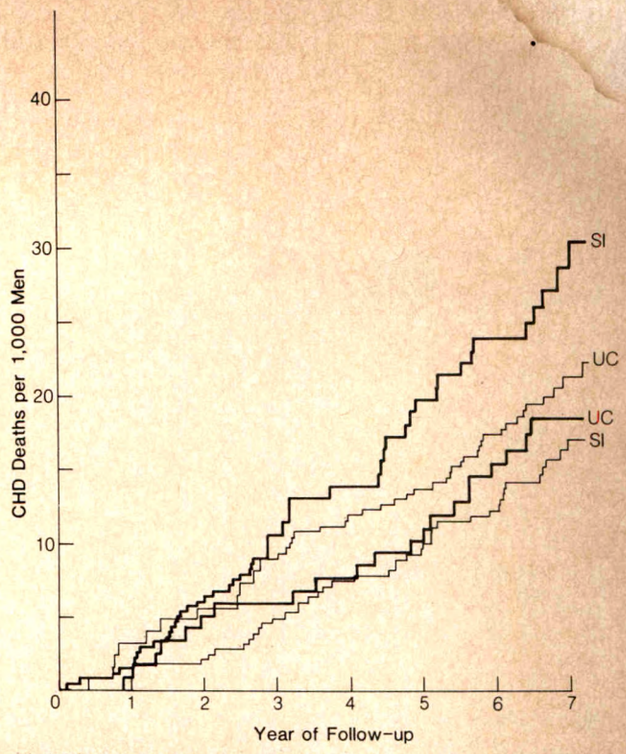

FIGURE 1. Cumulative coronary heart disease (CHD) mortality rates for hypertensive men in the special-intervention (SI) and usual-care (UC) groups according to the presence or absence of electrocardiographic (ECG) abnormalities at rest. The **heavy line** indicates men with baseline ECG abnormalities at rest and the **thin line** indicates men without ECG abnormalities at rest.

unity, although not nominally significant (p = 0.08 by Cox regression). This finding suggests that the higher relative risk (SI/UC) among men with ECG abnormalities at rest is concentrated among those who were hypertensive at baseline. Therefore, the CAD mortality rate for hypertensive men only, with and without ECG abnormalities, was compared for SI and UC men (Fig. 1). In hypertensive participants with ECG abnormalities, the cumulative mortality curves for the SI and UC groups were not significantly different (p = 0.06 by log-rank test). However, the estimated difference in the relative risks of CAD death (SI/UC) for hypertensive men with (1.67) and without (0.76) ECG abnormalities at rest is nominally significant (p = 0.02) by Cox regression.

The distribution of ECG abnormalities by main categories of the Minnesota code is shown in Table III. High R waves occurred in 39% of those with abnormalities, almost exclusively with a left-sided pattern (M.C.3.1, 3.3). Other categories found in at least 10% of those with ECG abnormalities were intraventricular conduction defects, negative T waves, arrhythmias and left-axis deviation. The percentage of participants with high R waves was directly related to diastolic BP at

S_2 = second screening visit; SI = special intervention; UC = usual care.

baseline, as was the percentage with negative T waves and the percentage with ST depression ($p < 0.01$ for linear trend for each); other abnormalities were not associated with baseline BP.

Accordingly, SI-UC mortality was compared separately in those with R or ST-T-wave abnormalities and in those with other abnormalities (Table IV). The 65% higher CAD mortality rate (relative risk of 1.65, similar to the adjusted relative risk of 1.67 in Table II) among hypertensive men in the SI group with ECG abnormalities at rest compared with those in the UC group contrasts with lower SI than UC rates in hypertensive men without abnormalities and in nonhypertensive participants. The estimated relative risk (SI/UC) for hypertensive men is larger, but not significantly so, in those men with R- or T-wave changes (1.71) compared with men with other ECG abnormalities (1.55), both being larger than the relative risk in hypertensive men with no ECG abnormalities at rest (0.76). UC hypertensive men with ECG abnormalities at rest had a lower CAD mortality rate (17.7 per 1,000) than those without abnormalities (20.7 per 1,000), in contrast with the parallel comparison in UC nonhypertensive men (25.7 vs 16.1 per 1,000).

In the earlier report,[1] the relative risk of CAD death and death from any cause (SI/UC) was noted to increase with decreasing baseline diastolic BP among hypertensives, with an indication of a possible adverse effect in the SI group among those with entry levels of 90 to 94 mm Hg. The test for linear trend of relative risk estimates (SI/UC) yielded a nominal p value of 0.11 for CAD death and 0.001 for death from any cause. The cross-classification of SI and UC by level of baseline diastolic BP and ECG abnormalities at rest is given in Table V. At each level of baseline diastolic BP among hypertensive men, the relative risk (SI/UC) estimate for men with ECG abnormalities is larger than that for men without ECG abnormalities. Also, among men without as well as men with ECG abnormalities at rest, the relative risk (SI/UC) of CAD death is lower at the higher levels of baseline diastolic BP, with an estimate of 1.0 at a BP of 100 mm Hg or higher in those with abnor-

* Excluded from this table are 135 SI and 142 UC men with ischemia during rest, among whom there were 5 SI and 2 UC CAD deaths, and 284 SI and 288 UC men who did not participate in the exercise test, among whom there were 9 SI and 11 UC CAD deaths.
CAD = coronary artery disease; SI = special intervention; UC = usual care.

malities. Although the apparent increased risk of SI men at the lower diastolic BP levels compared with UC does not appear to be explained by the findings regarding the ECG abnormalities at rest, the numbers of deaths at each level of diastolic BP are small.

An expanded comparison of cause-specific mortality for hypertensive participants is shown in Table VI, by presence or absence of ECG abnormalities at rest. The greater number of SI than UC CAD deaths in the presence of ECG abnormalities at rest was concentrated among sudden deaths occurring within 1 hour (life-table Z value for SI vs UC hypertensive men with ECG abnormalities at rest of 2.34, nominal $p = 0.02$). In hypertensive men with ECG abnormalities there were no SI-UC differences in numbers of deaths from myocardial infarction or in sudden death from 1 to 24 hours. The numerical difference in total mortality in this subgroup (74 SI vs 47 UC deaths) is nominally significant ($p = 0.02$), and is twice as great as for CAD deaths alone, resulting from a few more SI than UC deaths in each category of non-CAD death (other cardiovascular disease, noncardiovascular disease, and unknown cause). In the absence of ECG abnormalities there were fewer SI than UC deaths (life-table $Z = -1.49$, $p = 0.14$), mainly from cardiovascular disease, but with no apparent difference in deaths from myocardial infarction or stroke.

The increased relative risk (SI/UC) for hypertensive participants with ECG abnormalities at rest compared with similar men without ECG abnormalities at rest and to normotensive men has also been examined with stratification based on presence of ECG abnormalities during exercise. Among men who participated in the exercise ECG (95.6% of all randomized men), the percent of participants with an abnormal ECG during or immediately after the exercise test, using the computer criteria (see Design and Methods section), was 12.2%. A positive response was strongly related to risk of CAD death in the UC group (Table VII). Comparison of SI-UC differences revealed that when baseline ECGs both at rest and during exercise were abnormal, for both hypertensive and normotensive participants, SI rates were considerably lower than UC rates (row 4, Table VII). The SI-UC differences were larger when the exercise ECG was abnormal and the electrocardiogram at rest was normal (row 3). When the electrocardiogram during exercise was normal and the electrocardiogram at rest was abnormal, the CAD mortality rate of hypertensive men in the UC group was unexpectedly low, only 8.2/1,000/7 years, and the SI rate was much higher

TABLE VIII Number and Rate (per 1,000 person-years) of Coronary Artery Disease Deaths for Multiple Risk Factor Intervention Trial Participants in the Special-Intervention Group by Hypertensive Status at Baseline, by the Presence of Baseline Electrocardiographic Abnormalities at Rest and by Diuretic Therapy at Last Annual Visit

	Baseline Rest ECG Abnormalities					
	Present			Absent		
Hypertension and Treatment Status	Person-years	No. of Deaths	Per 1,000 pers.-yrs.	Person-years	No. of Deaths	Per 1,000 pers.-yrs.
Hypertensive at baseline						
On diuretic	5,737	34	5.93	12,376	28	2.26
Not on diuretic	2,637	2	0.76	6,772	16	2.36
Total	8,374	36	4.30	19,148	44	2.30
Nonhypertensive at baseline						
On diuretic	696	4	5.75	2,023	5	2.47
Not on diuretic	3,437	7	2.04	10,584	19	1.80
Total	4,133	11	2.66	12,607	24	1.90
All						
On diuretic	6,433	38	5.91	14,399	33	2.29
Not on diuretic	6,074	9	1.48	17,356	35	2.02
Total	12,507	47	3.76	31,755	68	2.14

The relative risk (diuretic/no diuretic) in the presence of ECG abnormalities at rest is 3.99 (5.91/1.48); the corresponding relative risk in the absence of ECG abnormalities at rest is 1.13 (2.29/2.02).

than the UC rate (row 2). Among nonhypertensive men in this subgroup, as well as in hypertensive and nonhypertensive men with neither rest nor exercise ECG abnormalities (row 1), CAD mortality rates were similar with only small SI-UC differences.

Overall statistical comparison of the joint effect of ECG findings at rest and during exercise suggests that these were independent influences on the differences in CAD mortality between the SI and UC groups ($p = 0.96$ for test of hypothesis of dependence, for hypertensive and nonhypertensive men combined). Specifically, for the total group, among men with a normal ECG during exercise, the relative risk (SI/UC) of CAD death was 0.98 (14.6/14.9) for men with a normal ECG response at rest and 1.89 (20.0/10.6) for men with an abnormal ECG response at rest, the latter relative risk being approximately twice as large as the former. For men with an abnormal ECG response during exercise, the corresponding relative risk estimates were 0.32 and 0.57. Again, the relative risk (SI/UC) for men with ECG abnormalities at rest was approximately twice as large as the corresponding estimate for men with a normal ECG response at rest. However, as noted above, a net adverse effect was apparent only for hypertensive SI men with a normal exercise test response and an abnormal ECG at rest.

Coronary artery disease mortality in subgroups defined after randomization—antihypertensive treatment: The findings in subgroups defined by baseline characteristics pose a possible problem with the hypertension intervention program for men with baseline ECG abnormalities at rest. Since drug treatment was the primary means of lowering BP for SI participants, the question was examined as to whether some aspect of the pharmacologic treatment or some consequence thereof, was associated with an increased CAD risk for men with ECG abnormalities at rest. To do so, within-group analyses based on factors occurring postrandomization had to be used; these do not preserve the randomized design of the trial and are more subject to bias by confounding variables.

As previously reported,[1,11] drug therapy was widely used in both SI and UC groups, with 58% of SI and 47% of UC participants prescribed medication by the 6-year follow-up. Even in participants with baseline diastolic BP less than 90 mm Hg, there was a gradual increase in the use of medication during follow-up as participants with borderline levels reached the criterion for hypertension. The prevalence of drug treatment in such men was 26% in the SI and 18% in the UC group at the sixth annual visit. In both SI and UC groups, treatment was slightly more frequent in those with than in those without ECG abnormalities (Table I). Those with abnormalities also had a mean baseline diastolic BP 1.5 mm Hg higher than those without (Table III).

Because of different patterns of use of specific diuretics, including dosage, in the SI and UC groups, relations of treatment variables with ECG abnormalities and CAD mortality are discussed separately. The data for SI participants were subdivided by presence of hypertension at baseline (Table VIII) as a means of controlling for entry level BP differences between men subsequently prescribed and those not prescribed a diuretic drug. In both of the strata SI men with baseline ECG abnormalities had a higher CAD mortality rate if they were receiving diuretic drugs at their most recent annual examination than if they were not (5.93 vs 0.76 and 5.75 vs 2.04 per 1,000 person-years, for hypertensive and nonhypertensive subgroups, respectively). No such differences were seen in the absence of ECG abnormalities, the CAD rates exhibiting remarkable similarity for those taking and those not taking diuretic drugs.

SI participants not prescribed diuretic drugs do not represent an ideal comparison group for those receiving these drugs even among hypertensive participants. A few not taking diuretic drugs were prescribed other antihypertensive medications. Most BP levels became normal during the study; much of this effect was due to

TABLE IX Number and Rate (per 1,000 person-years) of Coronary Artery Disease Deaths for Multiple Risk Factor Intervention Trial Participants in the Special-Intervention Group Before April 1, 1980, by Presence of Baseline Electrocardiographic Abnormalities at Rest and by Type and Dose of Diuretic Drug at Last Annual Visit

weight reduction or regression toward the mean. A few participants remained hypertensive but refused drug therapy. For the comparison of the relative risk of CAD death (diuretic/no diuretic) among men with ECG abnormalities at rest and men without these abnormalities, this potential bias is minimized, because there is no evidence that compliance or BP lability differs among men with compared to men without ECG abnormalities at rest.

The hypothesis that the relative risk (diuretic/no diuretic) of CAD death differed for SI men with ECG abnormalities compared with SI men without baseline ECG abnormalities at rest was tested using Cox regression models with previously defined covariates (see Design and Methods section). The first model assumed no interaction of diuretic use and baseline ECG abnormalities at rest. The analysis revealed a positive association of each of the entry level risk factors with CAD death, an association of cigarette smoking cessation ($p = 0.01$) and cholesterol reduction ($p = 0.007$) with a decreased CAD mortality, and an association of baseline ECG abnormalities at rest with an increased CAD mortality rate ($p = 0.02$). The association of diuretic use and CAD mortality was positive but not significant ($p = 0.07$). The second model allowed the association of diuretic use with CAD death to vary according to the presence of ECG abnormalities at rest (i.e., an interaction was postulated). Coefficients for the risk factors and their changes were virtually identical to the first model. However, this model indicated that the association of diuretic use with death from CAD depended on the presence of ECG abnormalities at rest ($\chi^2(1) = 8.90$, $p = 0.003$ for interaction). In the presence of ECG abnormalities at rest, the estimated relative risk of CAD for men prescribed a diuretic drug compared with men not prescribed a diuretic drug was 3.34. The corresponding relative risk estimate for men without ECG abnormalities at rest was 0.95. The relative risks estimated from such models separately for men hypertensive and nonhypertensive at baseline were similar. For hypertensive participants the interaction between diuretic use and ECG abnormalities at rest was significant ($p < 0.001$), while for men nonhypertensive at baseline it was not ($p = 0.30$).

In similar models with a term for change in diastolic BP instead of an indicator variable for diuretic, there was a trend in the SI group for BP reduction to be positively associated with an increased CAD mortality rate, but this association is not significant for either ECG subgroup (with abnormalities, $p = 0.15$; without abnormalities, $p = 0.40$).

In the UC group no significant interaction between diuretic treatment and ECG abnormalities at rest was found in men hypertensive at baseline ($p = 0.73$). The estimated relative risk of CAD death (diuretic/no diuretic), adjusted as in the analysis of SI mortality, was 1.25 for men with and 1.09 for men without ECG abnormalities at rest.

As already noted, there were major differences in the use of specific diuretic drugs and their dosage between the SI and UC group. The majority of UC participants receiving antihypertensive drugs were treated with hydrochlorothiazide. Many others were receiving similar thiazide diuretics, and at most annual examinations fewer than 10% were taking chlorthalidone. Most of those receiving hydrochlorothiazide were prescribed doses of 25 to 50 mg/day; for example, at the third annual visit, 34% of those taking hydrochlorothiazide were taking 25 mg and 53% were taking 50 mg.

In the SI group, the protocol permitted use of either hydrochlorothiazide or chlorthalidone, and over the course of the trial MRFIT clinicians used each with about the same frequency. Hydrochlorothiazide was used somewhat more often during the first 5 years, and chlorthalidone much more during the final 2 years as a result of the protocol change previously described. As to dose, SI participants were approximately equally divided between those taking 50 mg and those taking 100 mg of either diuretic through the fifth year.

The results of a person-years analysis relating CAD mortality to specific diuretic and dose levels, and to ECG abnormalities at rest, are shown in Table IX. For this analysis the follow-up period was terminated at March 31, 1980, a point at which approximately half of the conversion to chlorthalidone had occurred for SI participants previously prescribed hydrochlorothiazide. Use of this shortened follow-up period reduces the potential bias in comparing diuretics that could arise if a

Other drugs	324	4.4	3.1	668	4.2	7.0

particular diuretic was associated with an increased risk of CAD and that increased risk was not eliminated when the switch in drugs occurred. For men with ECG abnormalities at rest, the death rate for those taking hydrochlorothiazide at their last visit was 2.30 times higher than for men taking chlorthalidone. After adjustment by Cox regression for age, entry levels of the 3 risk factors, change in serum cholesterol and smoking cessation, the relative risk of hydrochlorothiazide to chlorthalidone was reduced to 1.90 ($p = 0.16$ for difference from 1.0).

For neither diuretic was there a trend toward increasing mortality rate at the higher doses in the presence of ECG abnormalities (Table IX). The Cox-regression-adjusted relative risks (>50 mg/≤50 mg) in the presence of ECG abnormalities were not significantly different from unity (chlorthalidone, 0.73; hydrochlorothiazide, 1.07). Dose was classified at the most recent annual visit; therefore, these relations could have been distorted by reduction of dose between annual visits because of symptoms or biochemical changes.

Several other explanations have been explored as to the apparent interaction between baseline ECG abnormalities and antihypertensive treatment in SI participants. The positive associations by Cox regression analysis between reduction in diastolic BP and CAD mortality in those with and without ECG abnormalities at rest were not significant, and there was no evidence for an interaction with ECG abnormalities. As to the use of other antihypertensive drugs, each of the step II drugs except for methyldopa was used more frequently in SI than UC participants, regardless of the presence of ECG abnormalities at rest (Table I). Moreover, the interaction between diuretic use and ECG abnormalities within the SI group was not affected by whether men were taking diuretics alone or in combination with another drug (largely the antiadrenergic step II drugs).

Possible mechanisms: Among the mechanisms suggested for the apparent adverse effect of diuretics in SI participants with ECG abnormalities at rest, the relation with hypokalemia has been the most extensively examined. Among participants taking antihypertensive drugs, the mean serum potassium level was slightly lower and prevalence of hypokalemia (serum potassium level less than 3.5 mEq/liter) was considerably higher in the SI than in the UC group; prevalence was twice as high at the fourth annual exam (Table X). This greater frequency of hypokalemia is explained by the higher doses of diuretic drugs used by men in the SI compared with the UC group and the greater use of chlorthalidone, more of a potassium-wasting drug than hydrochlorothiazide.

There was no association of hypokalemia (potassium level less than 3.5 mEq/liter) with CAD mortality in the SI group (Table XI), either for all men receiving antihypertensive drug therapy or for those with baseline ECG abnormalities: The prevalence of hypokalemia in all CAD deaths at their last annual visit was 15.7%, in those with ECG abnormalities at rest, 13.2%, and in survivors at 48 months, 23.0%. Previous tables have suggested different degrees of association of hydrochlorothiazide and chlorthalidone with hypokalemia and with CAD mortality; therefore, the data were also stratified by specific diuretic. Among participants taking each drug the numbers of deaths in men with hypokalemia at the last annual visit were few, but there was no indication of a higher prevalence of hypokalemia in men with ECG abnormalities who died than in similarly treated survivors (Table XI).

Because sudden death within 60 minutes accounted for much of the SI-UC difference in CAD mortality, analyses were undertaken of MRFIT data on arrhythmias identified on ECG tracings during annual visits. They have not suggested any association between baseline ECG abnormalities and cumulative incidence of any ventricular premature beats (VPBs) in men hypertensive at entry. Specifically, the incidence of VPBs was no different in hypertensive SI men with ECG abnormalities (10.8%) than in corresponding UC men (10.2%) or in hypertensive SI men who were free of ECG abnormalities (10.4%). The same was true when VPBs constituted at least 10% of recorded beats. However, VPB incidence in the SI hypertensive subgroup as a whole was higher than in UC hypertensive men (relative risk = 1.14); this contrasts with the relative risk (SI/UC) in nonhypertensive men (relative risk = 0.83; $p = 0.008$, for difference in relative risk estimates). Within-group analysis showed a positive association between diuretic use and VPB incidence among SI participants ($p = 0.05$)

TABLE XI Presence of Hypokalemia (Potassium Level Less than 3.5 mEq/liter, Most Recent Annual Visit) for Coronary Artery Disease Decedents and Survivors in the Special-Intervention Group at 48 Months of Follow-Up by the Presence of Baseline Electrocardiographic Abnormalities at Rest

by Cox regression with adjustment for age, the 3 risk factors at entry, smoking cessation and serum cholesterol change. However, the relative risk of CAD death after VPBs at any previous annual examination was not significantly different from unity for men with (1.24, p = 0.63) or without (1.15, p = 0.79) baseline ECG abnormalities at rest.

Discussion

The purposes of this report were to examine 1 of the 2 major MRFIT subgroup hypotheses, to explore data relevant to an apparent adverse effect related to this hypothesis, and to relate the findings to the overall MRFIT results. Before discussing the results from these perspectives, the strengths and limitations of the data must be considered. The hypothesis regarding the subgroup with a normal ECG at rest, as well as the main data analyses, were determined before the termination of the trial, as were the definitions of abnormal ECG responses at rest and during exercise. However, because subsequent analyses were in part suggested by inspection of the data, there is a greater possibility that the findings represent random variation. Moreover, a number of the critical analyses yielded probabilities that did not achieve nominal levels of significance even without adjustment for multiple subgroup comparisons. Also, although the initial analyses preserved the advantages of randomization, some of the analyses were carried out within the SI or UC groups using postrandomization factors. These are susceptible to bias due to confounding variables, although adjustment for known potential confounders did not weaken the findings.

A further problem with subgroup analyses in MRFIT derives from the fact that the observed numbers of deaths was far lower than expected based on the original study design. Several reasons have been given for this low mortality rate, including the volunteer effect, selection criteria, secular trends, and risk factor changes in both the SI and UC groups.[1] This smaller number of events reduced the statistical power to detect significant associations in subgroups, as it did for the overall trial results. Nevertheless, the findings reported herein suggest important effects of antihypertensive treatment that must be carefully considered.

Baseline-defined subgroups: The test of the hypothesis that in men without ECG abnormalities at rest, CAD mortality would be lower in the SI than UC group yielded suggestive, but not conclusive, results. When examined in the context of findings on the electrocardiogram during exercise, it appears that the very low mortality (compared with overall design expectations) for those with a negative exercise test response is a possible explanation for the failure to identify a substantial SI-UC difference in CAD mortality (Table VII). The mortality rate in the UC group was low among patients without a positive exercise test response, ranging from 8 to 17/1,000 over an average of 7 years among the subgroups, or approximately 1 to 2.5/1,000 per year. It would have required an unusual intervention effect to reduce the CAD mortality rate much below this level; on the same principle, any potential adverse effect may be more readily manifest. A major benefit from intervention was suggested only for men with an abnormal exercise ECG response, a group for which the CAD mortality was much higher than the group with a normal ECG response; details of these results, along with discussion of the pathophysiology of rest vs exercise ECG abnormalities, are the subject of a separate report.[2]

In men without ECG abnormalities during exercise, the SI-UC difference in CAD mortality in hypertensive men with ECG abnormalities at rest was 2.5-fold (row 2, Table VII). Interpretation of these differences involves assessment of the meaning of the unusually low rates in the UC hypertensive subgroup with ECG abnormalities at rest compared with UC men without ECG abnormalities at rest (e.g., 8.2/1,000 and 17.0/1,000 respectively, for those with a normal exercise ECG response). This observation contrasts with previous studies[16] that demonstrated an independent positive relation of similarly defined ECG abnormalities with CAD incidence. These studies have not stratified analyses by hypertensive status, but recently published data from the Chicago Heart Association Detection Project in Industry show a strong prognostic effect of ECG abnormalities on CAD and total mortality in hypertensive men demographically similar to MRFIT participants.[17] These relations clearly need more epi-

demiologic study, but several observations militate against dismissing the MRFIT data on the basis of this inconsistency between findings in the UC group and results of other studies: (1) The more numerous exclusions on the basis of medical history and ECG criteria in MRFIT, compared with observational cohort studies, may alter the distribution and prognostic significance of ECG abnormalities at rest in this selected group of men. (2) More intensive treatment of hypertension than existed in the general community during the 1960s and early 1970s, as occurred in both SI and UC groups, may modify the "natural history" relations. (3) Among SI men, nonhypertensive at entry, ECG abnormalities also exhibited little prognostic significance (Table IV), particularly in the absence of subsequent diuretic therapy—2.0 vs 1.8 CAD deaths per 1,000 person-years (Table VIII). (4) The within-group analyses are strongly suggestive of an unfavorable effect of antihypertensive treatment with diuretics in the SI subgroup with baseline ECG abnormalities at rest.

Antihypertensive drug treatment: There was a significant interaction ($p = 0.003$) between ECG abnormalities at rest and diuretic therapy in the total SI group, an effect that was not evident among UC participants. Results of within-group analyses among SI men using univariate (person-years) and multivariate (Cox regression) methods were consistent. Furthermore, the regression analyses, incorporating terms for the major risk factors at baseline as well as serum cholesterol change and smoking cessation, showed significant associations with CAD risk in expected directions, thereby increasing confidence in the model. In men in the SI group, the association among ECG abnormalities at rest, diuretic treatment and CAD death appeared consistent for both those with baseline hypertension and those with normal BP at entry, a substantial proportion of whom later became eligible for antihypertensive drug treatment. There was a suggestion of a stronger adverse effect of hydrochlorothiazide than chlorthalidone, but the difference did not achieve nominal significance in this analysis.

The evidence regarding the important question of a dose-effect was conflicting, and resolution is difficult, in part because there was considerable shifting of both dose and type of diuretic in SI participants during the trial. Since BP was controlled in the UC group reasonably well, often with a dose of hydrochlorothiazide of less than 50 mg (compared with 50 to 100 mg in the SI group), and no adverse interaction with ECG abnormalities was seen, a reasonable inference may be that the adverse effect in SI men was dose-related. However, there is no indication of dose-relatedness in the SI group from the analyses based on recent visits discussed in this paper, nor from analyses based on dose at a single annual exam early in follow-up (to allow for the possibility of a long latent period). These findings present an unresolved paradox: If not explained by the different dose distributions, why is the interaction of diuretic use and ECG abnormalities at rest not apparent in the UC group? If there is a dose effect, why can it not be detected in the SI group? One possible explanation is that the dose range in the SI group was too limited, since a 25-mg dose was not used. Differential adherence may be another factor; although UC men also reported frequent prescription of a 50-mg dose of hydrochlorothiazide, adherence to the prescribed regimen may have been less than that in the SI group. Finally, since data on UC drug treatment came largely from self-reports, it is probably less reliable than that for the SI group.

If the excess CAD and total mortality in this SI subgroup is real, the mechanism of action is not clear. In other studies, diuretic therapy has been associated with ventricular arrhythmias[18,19] and with sudden death among persons with preexisting heart disease.[20] Whether these relations depend upon hypokalemia is unclear.[19] Hypokalemia was more common in SI than UC participants receiving antihypertensive treatment, but in the analysis using potassium levels at the last annual visit, no relation to CAD mortality was demonstrated. Potassium levels were measured every 4 months and tended to be relatively stable over time. However, transient and unmeasured decreases in serum potassium may have occurred due to unusual environmental stimuli, as has been observed with experimental administration of epinephrine,[21] thus eliciting fatal arrhythmias in susceptible MRFIT men.

The predominance of sudden death within 1 hour as the main category showing an SI-UC difference in cause of death lends some credence to such a mechanism. Another basis for arrhythmic death may be a positive relation between diuretic therapy and blood levels of catecholamines, as reported by other investigators.[22] Although no differences in frequency of VPBs on annual electrocardiograms between SI and UC participants with baseline ECG abnormalities at rest or between SI men with and without abnormalities have been found, there was an apparent excess of VPBs in hypertensive participants in the SI group, and an association with diuretic use. This may have operated upon the background of baseline ECG abnormalities at rest to result in the difference of sudden deaths. The analyses reported do not support this hypothesis, but because ventricular ectopic activity is extremely variable over time[23] and extended ECG monitoring was not performed, the ability to test such a hypothesis is limited.

Various effects of diuretic drugs, as well as of other antihypertensive agents, on blood lipids have been extensively documented, and some of these could theoretically accelerate atherogenesis.[24] Diuretic treatment appeared to affect blood lipids in MRFIT,[25] although mean levels of blood lipids during follow-up were lower in SI than UC participants, except for equal levels of high-density lipoprotein cholesterol.[1] However, SI-UC differences regarding changes in lipid levels did not differ by the presence or absence of ECG abnormalities (Table I); furthermore, in hypertensive men in the SI group, the strength of the association between reduction in the serum cholesterol level and CAD mortality did not differ significantly according to presence or absence of ECG abnormalities.

How do these observations compare with results of other clinical trials? Few data are directly relevant. The efficacy of drug therapy for hypertension has been

documented in several clinical trials.[5,26,27] Much of the reduction in mortality rate has been related to primary hypertensive complications of stroke, congestive heart failure and ruptured aneurysm. There were relatively few deaths from these causes in MRFIT (fewer than 8% of all deaths), probably related to the modest degree of hypertension at baseline, the age group selected, and entry exclusions.[1] The MRFIT results cannot be used as a test of the efficacy of drug therapy in reducing such complications. The results rather relate mainly to the effects of antihypertensive treatment on CAD mortality, an effect in which benefit has not been conclusively shown in the published data from clinical trials.[5,26–29] In this regard, it is relevant that all these trials except for Hypertension Detection and Follow-up Program were low in power to test efficacy of antihypertensive drug treatment in preventing CAD death, and that findings of most, including MRFIT in the subgroup free of ECG abnormalities at rest, showed positive trends. The Hypertension Detection and Follow-up Program has recently reported a significant reduction in indexes of CAD in its stepped-care compared to referred-care group; the data for nonfatal myocardial infarction largely reflect self-reported events.[30]

The MRFIT cohort differed from previous study groups in several respects: The sample was not population-based, as in Hypertension Detection and Follow-up Program; most persons with major end-organ damage were excluded; there were few nonwhite persons and no women. However, the trial may have identified a subgroup of men likely to have a reduced benefit or adverse effect of diuretic therapy. Another controlled trial in a small sample of older men has suggested an adverse effect on CAD mortality of a thiazide diuretic, but this association was not examined with respect to ECG abnormalities or other risk characteristics.[31] Preliminary data from the Hypertension Detection and Follow-up Program have suggested no evidence of harm with respect to all-cause mortality, but an attenuation of benefit from stepped-care in the subgroup with hypertension in the 90 to 104-mm Hg diastolic range, with ECG abnormalities at rest and free of other end-organ damage.[32] The results of the large, placebo-controlled Medical Research Council Trial of Mild Hypertension, in which the active treatment alternatives are thiazide diuretic and a β-adrenergic blocker, may yield data that will further clarify these issues.[33]

Conclusions and Implications

(1) In an analysis based on a prior subgroup hypothesis, a 21% lower CAD mortality rate was found for SI compared to UC participants without baseline ECG abnormalities at rest ($p = 0.12$). The difference in the relative risks (SI/UC) between the subgroups with and without ECG abnormalities at rest suggested that risk factor intervention was more effective for men without than with abnormalities ($p = 0.08$ for difference in relative risk estimates).

(2) This finding was not a result of confounding by differential risk factor intervention (SI vs UC) according to the presence or absence of ECG abnormalities (Table I).

(3) The increased risk of CAD death (SI vs UC) among men with ECG abnormalities at rest was concentrated in participants who were hypertensive at baseline. The estimated adjusted relative risk of CAD death (SI/UC) was 1.67 for hypertensive men with ECG abnormalities at rest (Table II).

(4) High R waves were the most common ECG abnormalities, but these and other BP-associated codes were not differentially associated with higher CAD mortality rate in the SI group when compared with all other ECG abnormalities (Tables III, IV).

(5) The higher relative risk (SI/UC) of CAD mortality for men with ECG abnormalities at rest was not confined to a particular level of entry BP (Table V).

(6) The association of ECG abnormalities at rest and CAD mortality was manifested chiefly as sudden deaths within 60 minutes of being seen alive and apparently well (Table VI).

(7) The CAD mortality rate was lower in the SI than in the UC subgroup with both abnormal rest and exercise ECG responses (Table VII). However, the relation of CAD mortality with ECG abnormalities at rest appeared to be independent of the presence or absence of an abnormal exercise ECG, i.e., the relative effect on the risk ratio (SI/UC) was approximately the same among men with as in those without exercise ECG abnormalities, in that ECG abnormalities at rest were associated with some attenuation of the apparent SI benefit (compared with UC) in the presence of exercise-associated ECG abnormalities.

(8) A significant positive association of CAD mortality with the joint presence of ECG abnormalities at rest and diuretic treatment was found in the SI (Table VIII) but not the UC group. This interaction could not be explained by the amount of BP reduction or the use of other antihypertensive agents. There was a nonsignificant trend ($p = 0.16$) toward a greater association of increased CAD mortality with the use of hydrochlorothiazide than of chlorthalidone among men with ECG abnormalities at rest (Table IX).

(9) Based on several definitions of exposure, no association of CAD mortality in the SI group with dose of either diuretic could be found (Table IX).

(10) Hypokalemia was more frequent among men in the SI than in the UC group receiving diuretic treatment, but no more frequent at their last annual visit in SI men who died of CAD while on drug treatment than in survivors, irrespective of ECG abnormalities at rest (Tables X and XI). Hypertensive participants also had an increased relative risk (SI/UC) of VPBs compared with nonhypertensive men, but there was no difference based on ECG abnormalities at rest. Finally, there was no significant association between VPBs and CAD mortality.

The MRFIT findings relative to ECG abnormalities at rest emerged from further pursuing the results of analyses planned before the data were examined, and are thus not conclusive. However, they should be regarded as indicating a need for review and reassessment of therapeutic approaches for a subgroup of patients with less severe hypertension and ECG abnormalities at rest. Such reassessment should consider choices of

drugs and dosage, drug combinations, and the appropriate role of nonpharmacologic management as sole and as adjunctive therapy.

Exercise Electrocardiogram and Coronary Heart Disease Mortality in the Multiple Risk Factor Intervention Trial

MULTIPLE RISK FACTOR INTERVENTION TRIAL RESEARCH GROUP

The Multiple Risk Factor Intervention Trial (MRFIT), a coronary heart disease (CAD) primary prevention trial, examined the effect on the CAD mortality rate of a special intervention (SI) program to reduce blood cholesterol level, diastolic blood pressure and cigarette smoking in 35- to 57-year-old men. Half of the 12,866 participants were randomly assigned to usual care (UC) in the community. During 6 to 8 years of follow-up, the CAD mortality rate was 7% lower in the SI than in the UC group, a nonsignificant difference. An a priori subgroup hypothesis proposed that men with a normal electrocardiographic response to a heart-rate-limited exercise test would experience particular benefit from intervention. An abnormal response, defined as an ST-depression integral measured by computer greater than a predetermined voltage-time cutpoint, was observed in 12.5% of the men at baseline, and was associated with a 3-fold elevation in risk of CAD death within the UC group. In the subgroup with a normal exercise electrocardiographic response, there was no significant SI-UC difference in the CAD mortality rate (16.0 and 13.8 per 1,000, respectively, for SI and UC men). In contrast, there was a 57% lower rate among men in the SI group with an abnormal test result compared with men in the UC group (22.2 vs 51.8 per 1,000). The relative risks (SI/UC) in these 2 strata were significantly different ($p = 0.002$). These findings suggest that men with elevated risk factors who have an abnormal exercise test response may benefit substantially from risk factor reduction. (Am J Cardiol 1985;55:16–24)

The Multiple Risk Factor Intervention Trial (MRFIT) was a randomized primary prevention trial designed to test the effect of a multifactorial intervention program on the mortality rate from coronary heart disease (CAD) in 12,866 men aged 35 to 57 years. The previously reported mortality results of the MRFIT showed a nonsignificant 7% lower CAD mortality rate in the special-intervention (SI) compared with the usual-care (UC) group.[1]

Two major subgroup hypotheses related to the baseline electrocardiograms (ECGs) were formulated in the early stages of the trial. These were set out to test whether favorable SI-UC differences in CAD mortality and morbidity could be demonstrated in men who at entry into the trial had a normal ECG response at rest or a normal ECG response to exercise, respectively. These 2 subgroup hypotheses were based on the idea that in a primary prevention trial in men at high risk free of clinical CAD, intervention at an earlier phase of the evolution of CAD would be more effective than at a later (even though preclinical) phase of the disease. The subgroup analyses related to the ECG at rest are presented in a separate report.[2]

The objective of this report is to address the other subgroup hypothesis: Among men with a normal electrocardiographic response to exercise, the incidence of CAD death is significantly lower in the SI compared with the UC group. The analyses are based on computer-read exercise ECGs. Since their clinical value is not well established, the prognostic significance of a positive exercise response in the UC group is also presented. Because the main MRFIT findings regarding morbid CAD events have not yet been reported, analyses in this paper are confined to fatal CAD.

Methods

Study population: MRFIT was a randomized clinical trial that involved screening during 1973 to 1976 of 361,662 men, aged 35 to 57 years, at 22 participating clinical centers in the U.S. A total of 12,866 men without evidence of definite CAD by history, physical examination or ECG at rest were enrolled in the trial. The eligibility criteria, statistical design consid-

The Participating investigators and their institutional affiliations are listed in the Appendix. Manuscript received July 23, 1984; revised manuscript received September 10, 1984, accepted September 11, 1984.

erations, and methods have been described.[1,3] The selection criteria included the use of a multiple logistic risk function, derived from Framingham data, to estimate each prospective participant's risk of future CAD on the basis of serum cholesterol concentration, diastolic blood pressure and cigarette smoking. Men were screened to select those in the upper 15% (later 10%) of a risk score distribution based on Framingham data. During screening, men with evidence of CAD, serious life-limiting conditions, markedly elevated diastolic blood pressure (≥115 mm Hg), or very high serum cholesterol levels (≥350 mg/dl) were excluded from the trial. Certain electrocardiographic abnormalities at rest including major Q waves and complete bundle branch block, as well as the use of digitalis drugs, were additional reasons for exclusion.

MRFIT participants were randomly assigned to either of 2 groups: a special-intervention program (the SI group) consisting of counseling for cessation of cigarette smoking, advice on dietary practices to lower blood cholesterol level, and stepped-care drug treatment for hypertension; or a group referred to their customary sources of health care in the community (the UC group).

Electrocardiographic recording and analysis methods: ECGs were recorded at rest and during exercise directly on FM cassettes using Marquette 3500 recorders. The ECG at rest obtained at baseline and annually included 15 electrocardiographic leads: 12 conventional leads and the orthogonal XYZ Frank leads. Because of the requirement to record ECGs both at rest and during exercise in the same session, the commonly used modified limb electrode positions were used to record the 12-lead ECGs.[4] The modification involved location of the left and right arm electrodes in the infraclavicular fossae 2 cm below the lower border of the clavicle and medial to the border of the deltoid muscle. The left leg electrode was placed at the horizontal level of the iliac spine in the midclavicular line (below electrode V_4). This modification induced significant changes in the frontal plane QRS axis and limb lead ECG waveforms.[4] However, it was adopted to obtain a higher quality ECG during exercise.

The 9 leads chosen for exercise stress testing were CS_5, aVL, aVF, V_4, V_5, V_6, X, Y and Z. Recordings were obtained immediately preceding the exercise test, during the peak exercise state, during the immediate recovery state, and 3 minutes after termination of exercise. All nonexercise tracings were recorded with the participant in a sitting position. Each sequence of exercise leads was recorded for 10 seconds, 3 leads at a time.

A graded treadmill exercise test was performed with stepwise increase of the slope and speed until a target heart rate predetermined for each man was reached or until the test was terminated prematurely because of symptoms. Target heart rates were 160, 157, 155, 153 and 151 beats/min for the age groups 35 to 39, 40 to 44, 45 to 49, 50 to 54 and 55 to 57 years, respectively. These rates were based on the predicted 84% of maximal heart rate for men of this age.[5] The only reason for deviation from the exercise protocol was for early termination of the test. Reasons for early termination, if this occurred, were recorded as follows: inability to continue; observed ST-segment depression reaching 0.1 mV at 80 ms past the J point; certain arrhythmias; systolic blood pressure exceeding 250 mm Hg; decrease in systolic pressure with increasing level of exercise; and technical problems. The men were instructed to refrain from smoking for at least 1 hour and to fast for at least 2 hours before the test. The average fasting time was approximately 6 hours.

The FM cassettes recorded at the clinical centers were sent to the ECG center in Halifax, where the ECGs were analyzed by a computer program. Prefiltering was used with upper corner frequency of 125 Hz and a sampling rate of 500 samples/s per channel. Computer analysis was done with an electrocardiographic program that used selective averaging of complexes for noise reduction.[6] An interactive computer-graphics terminal was used to verify the quality of all exercise electrocardiographic data, whereby the operator could easily check computer measurements and reject leads with excessive residual noise.

The computer program analyzed records obtained during the preexercise period, during the last 30 seconds of the peak exercise state, and during both points in the recovery period (immediately and at 3 minutes afterwards).

The criteria for an abnormal (ischemic) electrocardiographic response to exercise, established before any of the present analyses were performed, were as follows: ST-segment depression 16 μV-s or more in peak exercise or immediate recovery records in any of the leads CS_5, aVL, aVF, or V_5, with ST-segment depression less than 6 μV-s in the above leads in the preexercise sitting record.

The ST-segment depression was measured as the voltage-time integral over the negative portion of the ST segment within the initial seven-sixteenths of the ST-T interval (Fig. 1). The voltage-time integral units (microvolt-seconds) can be easily related to conventional visual measurements by estimating the area of ST depression under the PR baseline. For instance, an average ST depression of 0.1 mV (or 100 μV) over a period of 0.10 second is equal to an ST depression integral of 10 μV-s (irrespective of the slope of the ST segment). The choice of seven-sixteenths of the ST-T segment for the upper time limit of this integral was made on an empirical basis: This time point corresponds to the best visual estimate of the de-

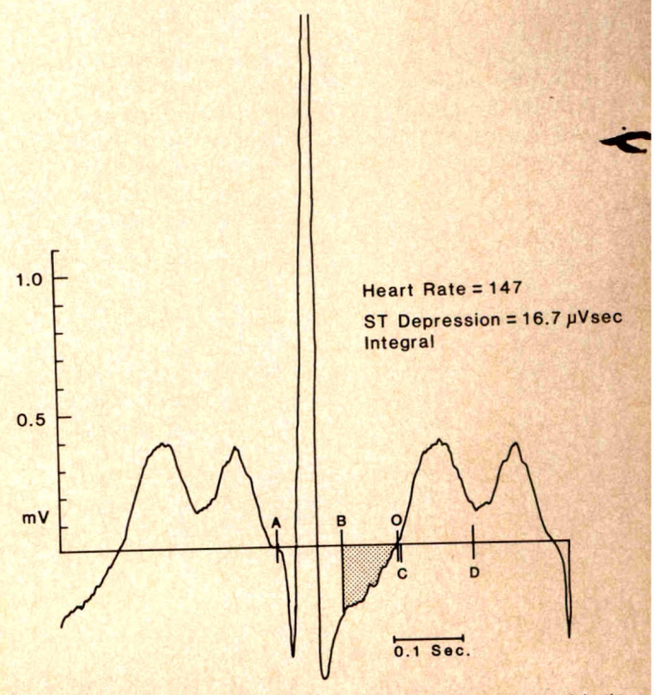

FIGURE 1. Definition of ST-depression integral (**shaded area**) is the time integral (in microvolt-seconds) of the electrocardiographic voltage from the end of QRS (**B**) to the zero crossing (0). If the ST segment is very slowly ascending or has a horizontal or downsloping course, the ST-segment area integration is terminated at the time point corresponding to seven-sixteenths of the total ST-T interval (i.e., BC = 7/16BD). The PR segment (**A**) immediately preceding QRS onset is taken as the baseline reference level for the integration. Measurements are made after clustering of all complexes, filtering and selective averaging.

TABLE I Number and Percent of Participants in the Multiple Risk Factor Intervention Trial Who Performed the Exercise Test and Reached Target Heart Rate and Reasons for Stopping Early

	SI		UC	
	n	%	n	%
No. randomized	6,428	100.0	6,438	100.0
Participated in exercise test	6,217	96.7*	6,205	96.4*
Reached target heart rate	5,176	83.3†	5,149	83.0†
Did not reach target heart rate, stopped early	1,041	16.7†	1,056	17.0†
Reasons for stopping early‡				
Leg discomfort, dyspnea, chest pain, fatigue, gait or speech disturbance	578	55.5	575	54.5
SBP ≥250 mm Hg	85	8.2	115	10.9
SBP decrease with exercise	14	1.3	7	0.7
ST abnormality (as judged by the attending physician)	200	19.2	185	17.5
Other ECG abnormalities (arrhythmias, etc.)	110	10.6	119	11.3
Technical and other problems	74	7.1	63	6.0

* Percent of those randomized.
† Percent of those who had an exercise test. All other percentages are of those who did not reach target heart rate.
‡ More than 1 reason could have been indicated.
ECG = electrocardiographic; SI = special intervention; SBP = systolic blood pressure; UC = usual care.

marcation point between the ST segment and the T wave, whenever it can be distinguished with reasonable repeatability. The 16-μV-s threshold for an abnormal electrocardiographic response to exercise was chosen before any analysis and represents a value 2 standard deviations above the mean for commonly used exercise leads,[6] with an upwards adjustment to account for the higher sensitivity (lead strength) of lead CS_5 used in MRFIT. The requirement that the preexercise ST depression must be less than 6 μV-s implies that the ST segment must increase at least 10 μV-s before it is called abnormal.

The computer ECG center in Halifax also reproduced paper tracings for visual coding. Because of anticipated problems of excessive noise, the visual analysis did not include a standardized reading of the peak exercise records, the customary point for clinical interpretation. Visual readings revealed a very low prevalence (<1%) of abnormalities (Minnesota code 4.1) during the period of recovery after exercise, as anticipated. Therefore, the subgroup findings in this report are restricted to analyses of the more prevalent abnormal test results from computer readings.

Statistical methods: The Kaplan-Meier product limit method[7] was used to compute the cumulative event rates for CAD death. Comparisons of survival (SI vs UC) for the subgroups defined by the presence or absence of abnormal electrocardiographic responses are summarized using the log-rank test.[8]

The Cox proportional hazards model[9] was used to assess the prognostic importance of exercise electrocardiographic abnormalities in the UC group after adjustment for other baseline risk variables. The Cox model was also used to assess the heterogeneity of the relative risk estimates (SI/UC) for men with and men without exercise electrocardiographic abnormalities and by risk factor level at entry.

The difference in risk factor levels and the use of antihypertensive treatment at 48 months between the SI and UC groups with and without abnormal exercise electrocardiographic response are summarized using Student t test for 2 independent samples and the normal approximation to the binomial distribution. Significance probabilities (p values) are unadjusted for multiple comparisons. Two-sided p values <0.05 are termed nominally significant.

Results of subgroup analyses in MRFIT should be viewed with caution, because the number of deaths observed overall was far smaller than expected based on the original study design. This smaller number of events reduces the statistical power to detect significant associations in subgroups.

TABLE II Crude and Adjusted Relative Risk Estimates for Participants in the Usual-Care Group with Exercise Electrocardiographic Abnormalities Compared to Men Without Electrocardiographic Abnormalities

	Crude RR	Adjusted* RR	p Value for Adj. RR	95% CI for Adj. RR
CAD death	3.75	3.44	<.0001	(2.31, 5.12)
All deaths	1.69	1.60	0.005	(1.15, 2.22)

* Using Cox regression for age, diastolic blood pressure, serum cholesterol concentration and number of cigarettes smoked per day.
CAD = coronary heart disease; CI = confidence interval; RR = relative risk.

Results

Of the 12,866 men enrolled, 12,422 (96.6%) participated in the baseline exercise ECG test (Table I). Men were excluded from the test if they had locomotor problems or ST-T changes on their ECG at rest as judged by the attending physician. (Participants with the voltage changes of left ventricular hypertrophy only were not excluded.) For men who had an exercise test, an equally high proportion (83%) in the SI and UC groups reached target heart rate (Table I). Reasons for terminating the test were similar in the 2 groups.

Prevalence of ischemic ST-segment response to exercise: In the group of 12,422 men who participated in the exercise test, the quality of the record was considered adequate for computer analysis in 12,294 participants (99.0%), and their tracings were analyzed. Of these, 276 men had a seven-sixteenths ST depression integral ≥6 μV-s in the preexercise sitting record and, therefore, did not meet the criterion for an abnormal electrocardiographic response to exercise. The overall prevalence of an abnormal ST-segment response to exercise, as a percent of those with available exercise data and a normal ST-segment response at rest, was 12.7% in the SI group and 12.2% in the UC group. This difference in prevalence was not significant. The contribution of various leads to overall prevalence will be addressed by a report in preparation.

TABLE III Number of Coronary Artery Disease Deaths and Cumulative Coronary Artery Disease Mortality Rate per 1,000 by Year of Follow-Up and the Presence or Absence of an Abnormal Exercise Electrocardiographic Response for Participants in the Multiple Risk Factor Intervention Trial*

	Exercise ECG Normal				Exercise ECG Abnormal			
	No. CAD Deaths		Cumulative Mortality per 1,000 Men		No. CAD Deaths		Cumulative Mortality per 1,000 Men	
Year	SI	UC	SI	UC	SI	UC	SI	UC
1	7	6	1.3	1.1	4	2	5.2	2.7
2	6	12	2.5	3.4	3	7	9.2	12.3
3	9	9	4.2	5.1	2	7	11.8	21.8
4	11	10	6.3	7.0	3	5	15.7	28.7
5	16	5	9.4	8.0	2	10	18.4	42.4
6	15	17	12.3	11.3	1	3	19.7	46.5
6-year total	64	59	—	—	15	34	—	—
As of 2/28/82†	84	73	16.0	13.8	17	38	22.2	51.8
Log rank Z statistic			0.9				−2.8	

* Two hundred eighty-three men in the SI group (9 CAD deaths) and 288 in the UC group (11 CAD deaths) who did not participate in the exercise test and 135 men in the SI group (5 CAD deaths) and 142 in the UC group (2 CAD deaths) with ST depression integral abnormal (≥6 μV-s) in preexercise rest sitting ECG are excluded from this mortality comparison.

† Average follow-up of 7 years.

CAD = coronary heart disease; ECG = electrocardiogram; SI = special intervention; UC = usual care.

Prognostic significance of computer-read exercise electrocardiograms: Men in the UC group with an abnormal ST-segment response to exercise had significantly higher death rates from CAD (51.8 vs 13.8 per 1,000) and from all causes (61.3 vs 36.2 per 1,000) than UC men without such a response. The CAD mortality rate was 3.4 times higher in men in the UC group with an ischemic exercise electrocardiographic response compared with men in the UC group without an ischemic exercise electrocardiographic response, after adjustment for age and baseline risk factors (Table II). The adjusted relative risk for all-cause mortality was 1.6.

Coronary artery disease mortality in SI and UC subgroups with normal electrocardiographic response to exercise: The left side of Table III shows the cumulative CAD mortality rate by year of follow-up among men in the SI and UC groups with a normal electrocardiographic response to exercise according to the computer criteria. At the end of the trial, with an average follow-up of 7 years, the cumulative CAD mortality rate was 13.8/1,000 in the UC group, compared to 16.0/1,000 in the SI group, a difference of +2.2/1,000. This relative SI-UC difference of 15.9% (95% confidence interval of +59.4% to −15.4%) is in a direction opposite to that hypothesized and is not statistically significant.

Coronary artery disease mortality in SI and UC subgroups with ischemic electrocardiographic response to exercise: The right side of Table III shows the cumulative CAD mortality rate by year of follow-up among men in the SI and UC groups with abnormal ECG response to exercise. The mortality rate was 51.8/1,000 among UC men, and 22.2/1,000 in the SI men, a difference of 57% (p = 0.007). The difference in the relative risk estimates (SI/UC) for CAD death for men with a normal exercise electrocardiographic response (1.16) compared with that for men with an abnormal exercise electrocardiographic response (0.43) is statistically significant (p = 0.002).

The cumulative CAD mortality curves are shown in Figure 2 for SI and UC subgroups with and without ischemia on the exercise ECG. After 2 years of intervention there was a sharp divergence in the mortality curves between UC and SI men with an abnormal exercise response.

Detailed causes of death by presence and absence of an abnormal exercise ECG response are given in Table

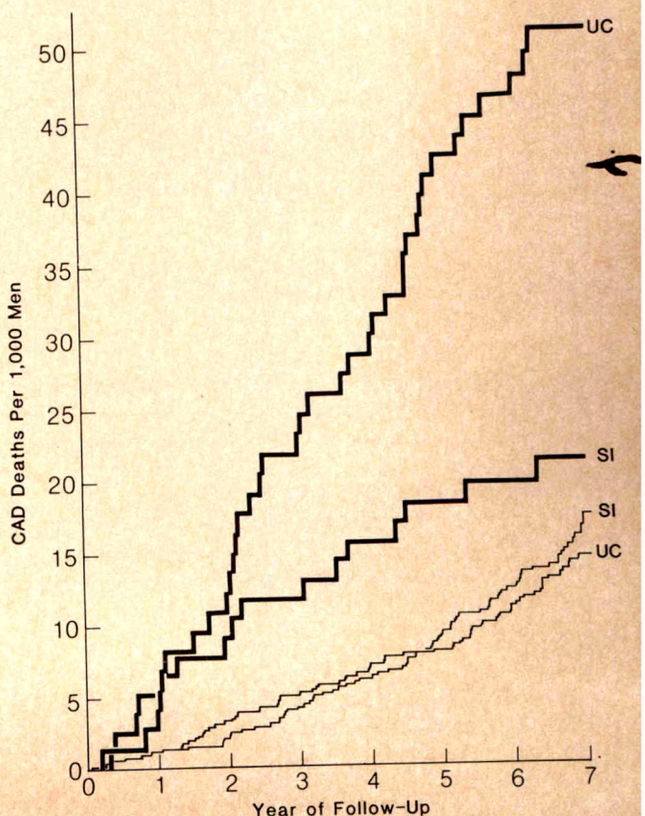

FIGURE 2. Cumulative coronary heart disease (CAD) mortality rates for participants in the Multiple Risk Factor Intervention Trial according to the presence or absence of an abnormal exercise electrocardiographic response. The **heavy line** indicates men with an abnormal baseline exercise electrocardiographic response and the **thin line,** men with normal exercise electrocardiographic response. SI = Special-intervention group; UC = usual-care group.

TABLE IV Number of Deaths by Cause (per 1,000) for Participants in the Multiple Risk Factor Intervention Trial by the Presence of Exercise Electrocardiographic Abnormalities at Baseline

	Exercise ECG Normal				Exercise ECG Abnormal			
	SI		UC		SI		UC	
Cause of Death	n	Rate	n	Rate	n	Rate	n	Rate
CAD	84	16.0	73	13.8	17	22.2	38	51.8
Myocardial Infarction	24	4.6	20	3.8	8	10.5	12	16.4
Sudden death <60 minutes	44	8.4	30	5.7	5	6.5	19	25.9
Sudden death <24 hours but ≥60 minutes	14	2.7	16	3.0	1	1.3	7	9.5

CAD = coronary heart disease; ECG = electrocardiogram; SI = special intervention; UC = usual care.

TABLE V Number of Coronary Artery Disease Deaths and Relative Risk Estimates (Special Intervention/Usual Care) According to the Maximum Level of ST Depression Integral for Participants in the Multiple Risk Factor Intervention Trial*

7/16 ST Depression Integral† (μV-s)	No. Participants		No. CAD Deaths (per 1,000)		Relative Risk (SI/UC)‡
	SI	UC	SI	UC	
<84	1,387	1,425	20 (14.4)	13 (9.1)	1.58
4–7.99	1,830	1,801	23 (12.6)	21 (11.7)	1.08
8–11.99	1,231	1,294	22 (17.9)	22 (17.0)	1.05
12–15.99	796	754	19 (23.9)	17 (22.5)	1.06
≥16	765	734	17 (22.2)	38 (51.8)	0.43
Total	6,010	6,008	101 (16.8)	111 (18.5)	0.91

* Restricted to participants with measurements during at least one stage of exercise.
† See text and Figure I for definition.
‡ p = 0.003 for significant trend in relative risk estimates.
CAD = coronary heart disease; SI = special intervention; UC = usual care.

IV. In the subgroup with abnormal response, the 57% SI-UC difference in CAD mortality is seen to reflect mainly lower SI rates of sudden death. Rates of non-CAD causes of death were somewhat higher in the SI than UC subgroup. However, the total mortality rate was approximately 50% higher in the UC ($p < 0.01$). In the subgroup with normal exercise electrocardiographic response, rates for various causes of death were similar for SI and UC groups.

Table V shows CAD death rates and relative risks (SI/UC) for 5 levels of ischemic ST-segment depression. The CAD death rates tended to increase with increasing levels of ST-depression integral for men in both groups, but more so for men in the UC group. A significant linear trend in the relative risk (SI/UC) estimates was noted ($p = 0.003$). The CAD mortality benefit in the SI relative to the UC group was only seen for maximal (≥16 μV-s) levels of ST-depression integral (relative risk of 0.43).

Relation of rest and exercise electrocardiogram to coronary artery disease and all-cause mortality: CAD and total mortality rates for men in the SI and UC groups with and without resting and exercise electrocardiographic abnormalities are given in Table VI. For men in both groups with normal electrocardiographic responses at rest and during exercise (the largest subgroup) CAD and total mortality rates were remarkably similar. The CAD death rate among UC men with an abnormal exercise electrocardiographic response but a normal electrocardiographic response at rest was 44.4 per 1,000, or about 3 times higher than the rate in the corresponding group of SI men (14.1 per 1,000). The SI rate is similar to that for SI and UC men with normal electrocardiographic responses at rest and during exercise. For men with abnormal exercise and rest electrocardiographic responses, the highest death rates were seen. A 43% lower CAD rate in the SI compared with UC group was not reflected in the total mortality rate. The direction of the SI-UC difference in the subgroup of men with a normal exercise and an abnormal rest electrocardiographic response was unfavorable to the SI group, i.e., the CAD death rates were 20.0 per 1,000 for SI men and 10.6 per 1,000 for UC men ($p = 0.048$).

The data in Figure 2 and Table IV, which document heterogeneity of relative risk (SI/UC) of CAD death according to the presence or absence of exercise electrocardiographic abnormalities, pose a question: Did men in the SI group with abnormal exercise electrocardiographic responses receive different intervention

TABLE VI Number (per 1,000 Randomized Participants) of Coronary Artery Disease Deaths and Deaths from Any Cause by Presence of Rest and Exercise Electrocardiographic Abnormalities for Participants in the Multiple Risk Factor Intervention Trial

Rest ECG	Exercise ECG	No. Participants		CAD Deaths		All Deaths	
		SI	UC	SI	UC	SI	UC
Normal	Normal	3,891	3,950	57 (14.6)	59 (14.9)	152 (39.1)	145 (36.7)
Abnormal	Normal	1,353	1,324	27 (20.0)	14 (10.6)	56 (41.4)	46 (34.7)

Thiocyanate adjusted quit rate	31.0	19.2	11.8	36.1	22.2	13.9	−2.1
Change in diastolic BP (mm Hg)	−9.0	−5.0	−4.0	−10.4	−5.8	−4.6	0.6
% prescribed antihypertensive drugs	55.1	38.4	16.7	60.0	48.2	11.8	4.9
% prescribed ≤50 mg chlorthalidone	8.5	2.9	5.6	10.0	3.5	6.5	−0.9
% prescribed >50 mg chlorthalidone	10.5	1.1	9.4	10.8	1.4	9.4	0.0
% prescribed ≤50 mg hydrochlorothiazide	15.7	20.1	−4.4	18.8	27.1	−8.3	3.9
% prescribed >50 mg hydrochlorothiazide	15.1	2.9	12.2	13.9	3.7	10.2	2.0
% prescribed reserpine	13.7	4.6	9.1	13.3	5.7	7.6	1.5
% prescribed methyldopa	5.4	6.2	−0.8	6.7	8.0	−1.3	0.5
% prescribed propranolol	10.3	5.0	5.3	13.9	7.1	6.8	−1.5
% prescribed hydralazine	6.7	3.0	3.7	7.5	4.5	3.0	0.7
Serum potassium change (mEq/l)	−0.3	−0.1	−0.2	−0.3	−0.1	−0.2	0.0

* None of these differences are statistically significant.
BP = blood pressure; ECG = electrocardiogram; HDL = high-density lipoprotein; LDL = low-density lipoprotein; SI = special intervention; UC = usual care.

or demonstrate different risk factor responses relative to similar men in the UC group than the men in the SI group with a normal exercise electrocardiographic response? Table VII displays risk factor changes and treatment characteristics of the 2 groups at 48 months by exercise electrocardiographic response. SI-UC differences for these multiple characteristics did not vary significantly by presence or absence of ischemia on the ECG.

Discussion

There were 3 main findings from these analyses. First, there was a substantial prevalence (12.5%) of an abnormal response to a heart-rate-limited exercise test using the computer-measured ST depression integral, despite having excluded men with evidence for overt CAD. Second, the abnormal response was highly predictive of CAD mortality in the UC group, with an adjusted relative risk of 3.44. Third, contrary to the hypothesis that the program would be especially beneficial in participants with a normal exercise ECG, no significant SI-UC difference in CAD mortality was found in this subgroup. However, among men with an abnormal exercise test a 57% lower rate of CAD mortality was observed in the SI compared with the UC group.

There were also unexpected findings related to the other subgroup hypothesis based on the ECG at rest, discussed in a separate report.[2] In the subgroup with normal baseline ECGs at rest, the SI group had a lower CAD mortality rate than the UC group, although the difference was not significant. In contrast, men in the SI group with abnormal ECGs at rest had a tendency toward a higher CAD mortality rate than their UC counterparts. This indication of a possible unfavorable outcome of the intervention program in the presence of an abnormal electrocardiographic response at rest was limited to men who were hypertensive at entry, in whom SI men had CAD mortality 65% higher than UC men.

These subgroup observations appear to be difficult to reconcile. However, the favorable response (SI vs UC) of abnormal exercise responders was independent of the unfavorable influence of an abnormal electrocardio-

graphic response at rest (Table VI). Apparently, there is a systematic difference in CAD death rates between the SI and UC group in favor of the SI among men with an abnormal response to exercise. For CAD mortality, this difference is, to a certain degree, attenuated by the presence of ECG abnormalities at rest; for all-cause mortality, it is eliminated.

An abnormal electrocardiographic response to exercise was associated with advanced CAD in many studies of symptomatic patients and asymptomatic men.[10,11] Prevalence of abnormal tests varies as much as 40-fold, depending on age, sex, presence or absence of symptoms, definition of a positive exercise electrocardiographic response, and exercise protocol used.[10–13] No 2 studies are exactly comparable, so that the prevalence of abnormal exercise response based on the electrocardiographic criteria used in MRFIT cannot readily be compared with the findings of other studies.

The criteria used in this study for an abnormal ECG response to exercise differ from the conventional clinical electrocardiographic criteria for an ischemic response which require a horizontal or downsloping ST segment depressed from the J point by 0.1 mV or more. The ST-depression integral measures the ST-segment area under the PR baseline and classifies the response as abnormal whenever the estimated upper normal limits for the integral are exceeded, irrespective of the slope of the ST segment.[14]

The use of such a computer-read negative ST-segment voltage-time integral as a measure of abnormal ECG response to exercise was first suggested by Sheffield et al.[15] They used the measurement to discriminate between normal persons and patients with angina pectoris. A later study[16] indicated that with an increasing value for the negative ST-segment voltage-time integral after exercise, there is a graded increase in CAD as measured angiographically. In the present study a similar graded risk of CAD death during a 7-year period was found as the negative ST-segment voltage-time integral at maximal exercise increased among both groups. White middle-aged men in the Lipid Research Clinics Follow-up Study with a positive exercise tolerance test response (visual or computer coding, or both) had a 5 to 8 times higher CAD mortality rate than men who did not have a positive test response.[17] The independent predictive value of the positive exercise test response among MRFIT participants is analyzed in more detail in another report (submitted for publication).

Reduction of the CAD risk factors—cigarette smoking, elevated serum cholesterol, elevated blood pressure, and obesity—among men with ischemic changes noted in their ECG at rest by the Minnesota code criteria in another study[18] resulted in a significant reduction in 6-year CAD incidence and total mortality compared to a group of similar controls not receiving intervention. In that same study there was no significant difference in 6-year CAD incidence among men without ischemic electrocardiographic changes at baseline between the intervention and the control group. Therefore, at least over a period of 6 years, benefit from risk factor reduction in middle-aged men is likely to be greater among those symptom-free men with ischemia revealed by the ECG than in those without this finding. This interpretation does not address the value of an early population-wide primary prevention strategy.

A possible explanation of the lack of significant difference in CAD rates between UC and SI groups among normal responders on both rest and exercise ECGs could be low statistical power. As illustrated by the observed confidence interval, any effect of intervention would be unlikely to be observed in a sample of this size among men with lesser degrees of coronary atherosclerosis at baseline, and therefore at low risk of CAD death.

The nature of the benefit among the abnormal exercise responders in MRFIT is reflected by an excessive number of sudden deaths in the UC compared to the SI group. The greater risk factor reduction may have resulted in a diminution or lesser progression of the atherosclerotic process in men in the SI group compared with those in the UC group. This could have prevented some sudden deaths; the incidence of sudden death increases sharply with increasing severity of CAD. Acute pathophysiologic consequences of coronary narrowing may also have been reduced, for example by the greater smoking cessation in the SI group. Such questions regarding mechanisms may be clarified by planned analyses of CAD morbid events, i.e., nonfatal myocardial infarction and angina pectoris.

Is there any insight that can be gained from the contrast between the apparent benefit from risk factor intervention in those with an ischemic-type electrocardiographic response to exercise, and the suggestion of an adverse effect in men with electrocardiographic abnormalities at rest? The pathophysiology that underlies electrocardiographic abnormalities during exercise is different from that of electrocardiographic abnormalities at rest. The latter may be more strongly related to cardiac muscle changes associated with hypertension, while the electrocardiographic changes noted in abnormal exercise response are more strongly related to ischemia. Further analyses of other CAD risk factor intervention studies may help to clarify these issues, and additional trials may be necessary.

Relation of Antianginal Efficacy of Nifedipine to Degree of Coronary Arterial Narrowing and to Presence of Coronary Collateral Vessels

WOLFGANG SCHULZ, MD, STEFAN JOST, MD, GISBERT KOBER, MD, and MARTIN KALTENBACH, MD

Thirty-six patients with chronic stable angina pectoris or with stable and vasospastic components of angina pectoris were classified by coronary arteriographic findings into 4 groups. Patients in group A had a single stenotic coronary artery; patients in groups B, C and D had occluded arteries, but these arteries had been collateralized to varying degrees, and an epicardial coronary steal phenomenon was possible. All patients underwent multiple exercise tests before and after randomized, double-blind, crossover treatment with 20 mg of nifedipine, 20 mg of isosorbide dinitrate, a combination of both, and placebo. Maximal and mean ST-segment depression, occurrence of angina pectoris and heart rate were evaluated. After nifedipine treatment, mean ischemic ST-segment depression was reduced 21% in group A ($p < 0.05$), but was not significantly altered in the other groups (group B, 2% decrease; group C, 10% increase; group D, 3% decrease). However, isosorbide dinitrate reduced ST-segment depression significantly in all groups (group A, 29%, $p < 0.001$; group B, 18%, $p < 0.01$; group C, 19%, $p < 0.05$; group D, 33%, $p < 0.05$). The combination with nifedipine did not further improve the effect of isosorbide dinitrate. Maximal ST-segment depression and angina pectoris paralleled the changes in mean ST depression during the different medications. Heart rate at rest was not significantly changed after nifedipine treatment in any group, but increased significantly after isosorbide dinitrate treatment in groups B and C (group B, 12%, $p < 0.01$; group C, 9%, $p < 0.05$); heart rate during exercise did not differ significantly in any group or after any form of medication from placebo. Thus, nifedipine fails to relieve myocardial ischemia if occluded but collateralized coronary arteries are present, indicating that the antianginal effect of this drug is influenced by underlying coronary pathomorphologic characteristics.

(Am J Cardiol 1985;55:26–32)

The antianginal potency of calcium channel blockers has been the subject of many studies and is generally accepted.[1–3] However, the reduction of angina pectoris and ischemic ST-segment depression vary greatly.[4] In some studies, some patients have not responded at all to nifedipine treatment, and this was mainly attributed to a reflex tachycardia resulting from a decrease in systemic blood pressure.[2,5,6] However, tachycardia is not present in all nonresponders.[4]

Some pharmacologists have reported that nifedipine can induce a "steal phenomenon" due to a malignant vasodilation[7–11]; others consider nifedipine to be a benign vasodilator.[12,13] An increase in flow to areas supplied by normal or stenotic coronary arteries is generally accepted. However, in compromised myocardium supplied only by collaterals, the flow alterations remain unclear. An increased flow at rest has been described and was attributed to a better collateral blood flow.[14] Theoretically, however, an impaired collateral flow may also be assumed, because a coronary steal phenomenon predominantly occurs, if a major coronary artery is occluded and the depending myocardium is collateralized.[15]

In the present study we assessed whether the response to nifedipine is related to coronary anatomy.

Methods

Thirty-six patients with angiographically documented coronary artery disease without transmural myocardial infarction, myocardial aneurysm or heart failure were classified according to their coronary anatomy (Fig. 1): *group A*—patients with 1 stenotic artery (at least 70% diameter reduction) in the left anterior descending, left circumflex or right coronary artery; *group B*—patients with 1 occluded artery collateralized by another artery without a diameter reduction of

more than 50%; *group C*—patients with 1 occluded artery collateralized by another coronary artery with a proximal obstruction of more than 60%; and *group D*—patients with 1 occluded artery collateralized by another coronary artery without significant stenoses (less than 50%), but with a stenosis of more than 70% diameter reduction in the third major coronary artery branch.

Coronary pathomorphologic characteristics, age, sex and applied workload are listed in Table I. The degree of coronary narrowing was taken as the average diameter reduction as seen from 2 or more projections after vasodilatation with 1.6 mg of nitroglycerin sublingually.

In all patients, an ischemic ST-segment depression of 2 mm or more could be induced by an individually adjusted workload in physical exercise tests; subsequently, the reproducibility of ST-segment depression was assured in 2 control tests with this workload. Angina pectoris during exercise testing was present in 67% of the patients. In addition, all patients were carefully questioned about anginal symptoms at rest, indicating a possible additional vasospastic component (Table II). These occasional symptoms at rest are a finding in many patients with coronary artery disease. However, they did not influence the reproducibility of anginal threshold and ST-segment depression during repeated exercise tests.

Patients were randomly assigned in a double-blind, crossover fashion with double-dummy technique to the following regimens: 20 mg of nifedipine, 20 mg of isosorbide dinitrate, a combination of 20 mg of nifedipine and 20 mg of isosorbide dinitrate, and placebo.

Regular antianginal therapy was discontinued 48 hours before the beginning of the study. As β-blocking drugs were not part of the regular antianginal therapy, a rebound was not expected. Only sublingual nitroglycerin was allowed for acute episodes of angina.

The exercise tests were performed 60 minutes after oral administration of the medications; in each patient the tests

were performed at the same time of day on 4 consecutive days according to the Kaltenbach protocol.[3] Workload and duration of exercise were kept constant during all 4 exercise tests in each subject. The ST-segment depression was manually measured and averaged out of 5 consecutive beats at each minute in leads V_4, V_5, V_6, I, II and III. The maximal ST-segment depression was determined, as was mean ST-segment depression, defined as average of ST depression during all minutes of exercise and 5 minutes of recovery. The onset and duration of angina pectoris (AP) were documented. Heart rate was averaged from 5 consecutive beats at the end of every minute during and after exercise. Statistical analysis was performed using Friedman's test and the subsequent analysis according to Wilcoxon and Wilcox.

Results

ST-segment depression: The severity of ischemic ST-segment depression showed significant differences among groups A, B, C and D after nifedipine administration, whereas after isosorbide dinitrate no significant differences were seen. Maximal levels of ST-segment depression are listed in Table III; maximal levels of ST-segment depression during exercise with each regimen are shown in Figure 2; mean levels of ST-segment depression are listed in Figure 3.

Nifedipine: In group A, 20 mg of nifedipine reduced mean and maximal ST-segment depression by 21% ($p < 0.05$) and 26% ($p < 0.05$), respectively. In group B, nifedipine reduced mean and maximal ischemic ST-segment depression by 2% (difference not significant [NS]) and 5% (NS)—a response similar to that during placebo treatment. In group C, in contrast, nifedipine increased mean and maximal ischemic ST-segment depression by 10% (NS) and 12% (NS), respectively. In group D, no significant changes of mean and maximal ST-segment depression were noted (decrease of 3% and increase of 5%, respectively).

Isosorbide dinitrate: Isosorbide dinitrate, 20 mg, diminished mean ST-segment depression in group A by 29% ($p < 0.001$), in group B by 18% ($p < 0.01$), in group C by 19% ($p < 0.05$), and in group D by 33% ($p < 0.05$).

Nifedipine and isosorbide dinitrate combined: The mean decreases in ST-segment depression after the combination were not significantly different from those during isosorbide dinitrate alone: group A, 34%; group B, 19%; group C, 24%; group D, 19%.

After treatment with isosorbide dinitrate or the combination of nifedipine with isosorbide dinitrate, the changes in maximal ST-segment depression paralleled the changes in mean ST-segment depression.

Angina pectoris: As a subjective measure of myocardial ischemia, the time of onset, the sum of all minutes with AP during and after exercise and the patients without AP were counted (Table IV). After nifedipine treatment, in group A, AP had a later onset and decreased duration; 1 patient who had AP after placebo did not show angina after nifedipine. In groups B, C and D, however, AP occurred slightly earlier and the duration was prolonged; 1 patient in group C who did not have AP after placebo had it after nifedipine. After isosorbide dinitrate treatment, AP occurred later or not at all in the groups A, C and D, and the duration decreased slightly. The effects of the combination were comparable to those after isosorbide dinitrate treatment alone.

ISDN = isosorbide dinitrate; N = nifedipine; NS = not significant; SD = standard deviation.

Heart rate: The mean heart rate at rest and during and after exercise is shown in Figure 4. Heart rates at rest were slightly higher in the treatment groups; these values were not significantly different from placebo except after isosorbide dinitrate treatment in group B and C (group B, 12% increase, $p < 0.01$; group C, 9% increase, $p < 0.05$). During exercise, no significant changes in heart rate were noted. During nifedipine treatment neither a reflex tachycardia at rest nor a higher increase

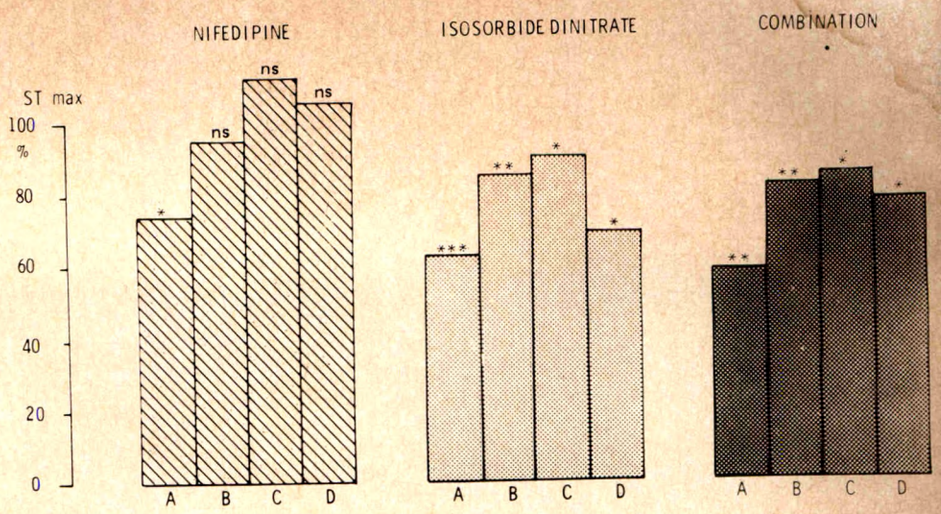

FIGURE 2. Maximal ST-segment depression during exercise tests after treatment with different medications in the 4 groups compared to placebo. ns = not significant.

in heart rate during exercise was noted in any patient in group B, C or D.

Discussion

Conflicting results concerning the antianginal potency of nifedipine have been reported. A higher exertional ST-segment depression was reported by Loos and Kaltenbach[1] in 1 of 18 patients, Becker et al[5] in 2 of 11 and Kober et al[2] in 2 of 10 patients; an exacerbation of anginal symptoms was reported by Stone et al[6] in 100 of 716 patients. In our clinical experience, nifedipine fails to relieve exertional angina in 10 to 20% of the patients. This was partially ascribed to a reflex tachycardia due to a decrease in systemic blood pressure. However, Fox et al[4] reported about nonresponders to nifedipine therapy without important changes in heart rate. The present study confirms these observations. We examined whether there is evidence for a "coronary steal" phenomenon as the cause for the lack of response to nifedipine.

Fam and McGregor[16] and Schaper et al[17] described a myocardial steal phenomenon after application of an arteriolar vasodilator (dipyridamole) that is induced by inhibition of coronary arteriolar autoregulation. This reduction in coronary resistance may induce myocardial ischemia by directing flow from an underperfused area to normally perfused myocardium. McGregor[18] stated

ISDN = isosorbide dinitrate; N = nifedipine.

that the coronary steal phenomenon "could, of course, only occur if the input was restricted" (Fig. 5). However, the precise conditions were controversial,[19,20] until Becker et al[15] demonstrated with dipyridamole treatment in dogs, that the coronary steal phenomenon occurs, if collateral vessels supply myocardium behind coronary occlusions and even more, if the collateral providing vessel is proximally stenotic.

An inhibition in metabolic autoregulation after nifedipine administration can also be assumed after intravenous or intracoronary injections, as judged by the increase in coronary flow[21] or coronary sinus oxygen saturation[22]; after sublingual application a smaller but longer-lasting increase of the coronary sinus oxygen saturation was found in dogs[12] as well as in humans.[8]

For this study, groups of patients with and without collateral vessels were selected. The hypothesis was that in patients without collateral vessels, nifedipine would be effective, whereas in patients with collateral vessels, a coronary steal phenomenon could diminish the antianginal efficacy of nifedipine.

The antianginal efficacy in patients without collateral vessels may be explained by dilatation of "dynamic" coronary stenoses. Significant widening of critical

stenoses has been shown by several investigators,[21–23] and a better oxygen supply improved the efficacy of nifedipine.[24]

Among patients in group B(as defined in Methods), a reduction of myocardial ischemia with significant reduction of AP or ST-segment depression was not seen. Antianginal mechanisms often cited to explain the efficacy of nifedipine are reduction of afterload, improved collateral flow or metabolic effects on the myocardium are not sufficient in group B patients to reduce myocardial ischemia.

Changes in afterload do not correspond well to the antianginal efficacy of nifedipine, and some paradoxical reactions have been described; the blood pressure during exercise may be even higher, when the antianginal effect is present, and even lower when nifedipine is ineffective.[21,24,25] In the present study, blood pressure was not measured and this may limit our conclusions. However, the blood pressure reaction to nifedipine was grossly uniform in patients who were normotensive. Some differences in blood pressure alone would hardly explain the ineffectiveness of nifedipine in the selected patients in groups B, C and D; 17 of 25 patients showed an unchanged or even worse maximal ST-segment depression. But the possibility cannot be excluded that a low blood pressure response aggravates the negative effects in patients prone to a steal phenomenon, as proposed by Hintze and Vatner.[26]

Improved collateral flow after nifedipine has been shown in dogs[27,28] after coronary ligation. During physical exercise in men, however, there was no improvement of ST-segment depression. Thus, an increase in collateral flow is apparently of no importance.

A metabolic effect on the myocardium was postulated to explain the antianginal efficacy of intracoronary nifedipine[29] and a metabolic effect has subsequently been proved.[21] In patients with coronary occlusions and collateral vessels, however, these possible beneficial effects on ischemia are overcome by the adverse effects of the coronary steal phenomenon.

If input is even more limited in patients in group C, 3 vascular effects may interfere after nifedipine therapy: dilation of epicardial coronary stenosis and dilation of epicardial collateral vessels are the favorable effects and dilation of metabolically regulated arterioles and capillaries in noncollateralized areas is an unfavorable effect. Dilation of stenoses or dilation of collaterals was apparently not sufficient to overcome the unfavorable effect of nifedipine on resistance vessels in these patients.

The lack of antianginal effect of nifedipine in patients in groups B, C and D cannot be related to an abnormal response in heart rate. After nifedipine, heart rates at rest and during exercise did not differ significantly in any group.

Results with the dipyridamole test in men confirm the validity of the above anatomic classification in regard to the possible induction of a steal phenomenon: A positive test can only be provoked if an occluded but collateralized coronary artery is present (manuscript in preparation).

All different forms of coronary pathomorphology can be found in patients with chronic stable angina or with additional "vasospastic symptoms" of angina pectoris. Seven of 10 patients in group B, 7 of 10 in group C and 4 of 5 in group D had symptoms indicating a vasospastic component of angina (Table II). Although it is generally assumed that nifedipine is especially effective in these patients,[30] it was not in patients with the coronary pathomorphologic characteristics of groups B, C and D. This finding again corresponds well to the clinical observation that nifedipine fails to relieve angina pectoris even in some patients with vasospastic components of angina.[6]

This study demonstrates the influence of coronary pathomorphology on the antianginal efficacy of nifedipine. For the first time, morphologic characteristics have been defined that influence the therapeutic efficacy of a calcium-blocking drug. The dependency on coronary anatomy may have important consequences in regard to antianginal therapy. Although in some patients dilation of coronary stenoses may be an important part of the antianginal efficacy of calcium-channel blocking agents, in other patients the occurrence of a steal phenomenon may diminish, abolish or even reverse its effect. It should be emphasized that the antianginal effect of nitrates, on the other hand, was preserved and grossly uniform in all 4 groups. Nitrates do not affect resistance vessels; they may dilate dynamic coronary stenoses and improve collateral flow by either direct or indirect mechanisms, especially by reducing preload variables.

Coronary Hemodynamic and Metabolic Effects of Nifedipine in Patients with Coronary Artery Disease Treated with Beta-Blocking Drugs

PETER SCHANZENBÄCHER, MD, GERHARD GÖTTFERT, MD, GERHART LIEBAU, MD, and KURT KOCHSIEK, MD

In humans, reflex sympathetic nerve activation modulates the direct cardiac action of nifedipine after systemic administration and results in a positive chronotropic and inotropic response. The coronary hemodynamic and metabolic effects of nifedipine were evaluated after propranolol-induced acute β-receptor blockade in 12 patients with angiographically documented coronary artery disease. The intravenous injection of propranolol led to a decrease in heart rate, coronary blood flow and myocardial oxygen consumption and an increase in coronary vascular resistance and the coronary arteriovenous oxygen difference. Mean aortic pressure did not change. The subsequent intravenous administration of nifedipine resulted in a transient increase in coronary blood flow and a reduction in coronary vascular resistance and the coronary arteriovenous oxygen difference and a sustained decrease in mean aortic pressure and myocardial oxygen consumption without significant changes in heart rate. Thus, in the presence of β-receptor blockade, the positive chronotropic response to nifedipine is attenuated and nifedipine reduces myocardial oxygen consumption significantly. The vasodilatory effect of nifedipine is maintained and a potential propranolol-related inappropriate vasoconstriction may be reversed. The combination of nifedipine and β-receptor blocking agents may be useful in the treatment of patients with both effort-induced angina and angina related to changes in coronary vasomotor tone.

(Am J Cardiol 1985;55:33–36)

The calcium channel blocker nifedipine is being used widely in the treatment of symptomatic coronary artery disease (CAD). Nifedipine has a negative inotropic effect on isolated heart muscle preparations and is a potent vasodilator of coronary arteries and other vessels.[1] In man, intravenous nifedipine therapy reduces left ventricular afterload and increases myocardial blood flow transiently.[2] However, after systemic administration, nifedipine does not decrease myocardial oxygen consumption significantly.[2,3] In humans, a negative inotropic and oxygen-saving effect of nifedipine is evident only after local application in the absence of peripheral hemodynamic effects.[2,4,5] The discrepancy between clinical and experimental data has been explained as the result of compensatory sympathetic activation counteracting the direct myocardial effects.

A recent experimental study suggested that the positive chronotropic and inotropic response to nifedipine could be modulated by autonomic blockade.[6] Clinically, nifedipine is frequently used in combination with β-blocking drugs.[7–9] However, no information is available regarding the effects of this combination on the coronary circulation of patients with CAD. In the present study, therefore, we evaluated the acute coronary hemodynamic and metabolic effects of nifedipine after β blockade by propranolol.

Methods

Patients: The study was performed in 12 patients, 11 men and 1 woman, who were undergoing routine cardiac catheterization for angina pectoris. CAD was defined as a 70% diameter reduction of 1 or more major coronary arteries. Patient data are summarized in Table I.

Catheterization: Each patient gave informed consent for the procedures described herein. Drug treatment was withheld

for 24 hours before study. Right- and left-sided cardiac catheterization, single-plane ventriculography, and selective coronary angiography in multiple projections were performed using the femoral route. A preshaped coronary sinus catheter with 2 thermistors and bipolar pacing electrodes (type CCS-7U-90B, Wilton Webster Laboratories) was inserted from the right antecubital vein and positioned in the mid-coronary sinus. When connected to the Wilton Webster 2-channel Wheatstone bridge and a chart recorder, it allowed measurements of the coronary sinus blood flow by the thermodilution method.[10,11] Catheter positions were frequently documented on videotape throughout the study so that a constant catheter position could be maintained.

Protocol: There was at least a 15-minute interval between the last injection of contrast medium for diagnostic coronary angiography and coronary sinus blood flow measurements. Coronary sinus blood flow (CSBF), myocardial oxygen consumption (MVO_2) heart rate and aortic pressure were determined at rest. Propranolol, 0.1 mg/kg, was injected at a rate of 1 mg/min. Heart rate and aortic pressure were continuously monitored. Ten minutes after the intravenous injection of propranolol, measurements were repeated. Thereafter, 1 mg of nifedipine in a 10-ml solution was continuously infused over 2-minutes. CSBF, MVO_2, heart rate and aortic pressure were measured immediately after the completion of the infusion and 5 and 15 minutes later. No side effects were observed during or after the propranolol and nifedipine infusions.

Measurements and calculations: Coronary sinus blood flow was measured by the constant-infusion thermodilution technique.[10,11] Coronary sinus blood flow measurements were performed during continuous infusion of 5% dextrose in water at room temperature with a constant infusion rate of 36 ml/min maintained by a Harvard pump. Arterial and coronary sinus blood samples were simultaneously drawn for determination of oxygen content. Oxygen content was measured using a Lex-O_2-Con-K (Lexington Instruments Corp.). MVO_2 was calculated from the product of the arteriovenous oxygen content difference and coronary sinus blood flow (CSBF): $MVO_2 = CSBF \times (A_0O_2 - CSO_2)$, where A_0O_2 = arterial oxygen content and CSO_2 = coronary venous oxygen content. Coronary vascular resistance (CVR) was derived from the ratio of mean aortic pressure (PA_0) to CSBF: $PA_0/CSBF$.

Data before and after propranolol and nifedipine injection were compared and evaluated by paired Student *t* test.

Results

After propranolol administration, heart rate decreased from 73 ± 14 to 66 ± 9 ($p < 0.025$). Mean aortic pressure did not change significantly (115 ± 21 vs 116 ± 19 mm Hg). CSBF decreased from 117 ± 27 to 104 ± 26 ml/min and MVO_2 from 15.7 ± 2.6 to 14.0 ± 2.8 ml O_2/min ($p < 0.001$). CVR increased from 1.01 ± 0.22 to 1.17 ± 0.28 mm Hg/ml/min ($p < 0.001$). The decrease in CSBF was accompanied by a moderate but statistically significant increase in the arteriovenous oxygen difference, from 13.2 ± 1.9 to 13.5 ± 1.8 vol% ($p < 0.01$).

The subsequent intravenous injection of 1 mg of nifedipine reduced the mean aortic pressure from 116 ± 19 to 97 ± 20 mm Hg ($p < 0.005$). Heart rate averaged 79 ± 9 and was not significantly different from values at rest ($p < 0.2$). CSBF increased to 148 ± 30 ml/min ($p < 0.001$) and CVR decreased to 0.66 ± 0.07 mm Hg/ml/min ($p < 0.001$). MVO_2 decreased to 12.9 ± 3.0 ml O_2/min ($p < 0.005$) and the arteriovenous oxygen difference was reduced to 8.7 ± 1.7 vol% ($p < 0.001$).

Five minutes after the nifedipine injection, heart rate (73 ± 7 beats/min), CSBF (113 ± 31 ml/min), CVR (0.97 ± 0.21 mm Hg/ml/min) and the arteriovenous oxygen difference (12.5 ± 2.0 vol%) were not different from control values. Mean aortic pressure (106 ± 19 mm Hg) and MVO_2 (13.7 ± 3.2 ml O_2/min) were significantly reduced at 5 minutes and 15 minutes after the injection (108 ± 16 mm Hg and 13.5 ± 3.2 ml O_2/min, $p < 0.005$). Tables II and III list the individual changes in CSBF and MVO_2. In all patients CSBF flow decreased after propranolol and increased transiently after nifedipine administration. MVO_2 was consistently lowered by propranolol, but the response to nifedipine treatment was more variable. Whereas 8 patients showed a decrease in MVO_2 after nifedipine, 4 patients showed a moderate increase 2 minutes after the injection. The latter 4 patients also showed a pronounced increase in heart rate.

Discussion

Coronary and metabolic effects of propranolol: Propranolol produced a significant reduction in MVO_2 and an increase in CVR. These effects have been reported previously.[12–14] However, other studies have suggested that no significant change in CSBF occurs.[15] Propranolol decreased left ventricular oxygen utilization in our patients. Thus, the decrease in CSBF ap-

pears to be related primarily to reduced myocardial oxygen requirements. Decreases in cardiac index and left ventricular stroke work index, as well as reductions in indexes of left ventricular contractility, have been reported after propranolol administration.[16,17] These changes indicate reduced myocardial oxygen demand. Schang and Pepine[12] could not find significant propranolol-related changes in CSBF and MVO_2 when heart rate was maintained by atrial pacing. Their findings suggested that coronary vasoconstriction occurring after propranolol is predominantly an autoregulatory phenomenon.

However, in our patients we observed a moderate but significant increase in the arteriovenous oxygen difference after administration of propranolol. This increase in left ventricular oxygen extraction suggests that the propranolol-related increase in CVR is not a pure autoregulatory phenomenon and may indicate inappropriate vasoconstriction. Theoretically, acute blockade of vasodilatory β-adrenergic receptors may increase CVR by enhancing the α-adrenergic vasoconstrictor response. Orlick et al[18] reported important coronary arterial α-tonus at rest in patients with CAD, and exacerbation of angina pectoris by propranolol has been reported.[19]

A propranolol-related inappropriate vasoconstriction has been suggested by Wolfson and Gorlin,[14] but this finding was not confirmed by other investigators.[13,15,17] These conflicting results may be explained by differences in the distribution and density of α and β receptors in individual patients and differences in the sympathetic tone at rest. Pretreatment with β-blocking agents before the study may also be important. Changes in β-adrenergic receptor density in patients with heart failure during therapy has been reported.[20]

Coronary effects of nifedipine: In the presence of acute β-receptor blockade, nifedipine preserved its systemic and coronary arterial dilating effect. There was a marked and sustained decrease in mean aortic pressure and a pronounced but transient increase in CSBF. The increase in CSBF is in the range observed in patients without β-blocker treatment after intravenous administration.[2]

Because of the complex actio on coronary perfusion pressur poststenotic epicardial corona sistance, and intraluminal diste dividual patients may have a p nifedipine. We recently obser transient occlusion at the site of with associated angina pectoris ever, all patients showed an incr administration of nifedipine (T

The increase in CSBF was ac icant reduction in the arterioven This indicates temporary overper to basal levels within 5 minute ministration. Prolonged dilatio coronary arteries after nifedipir been documented; this implies t in a sustained relaxation of ep vessels, while intramural arteriol dilated.[2,5]

Metabolic effects of nifedipi acute β-receptor blockade by pr produced a significant and sus MVO_2. However, when nifedipine no detectable changes in MVO_2 h humans.[2,3] This is in contrast to studies.[1]

In conscious animals and in hu diac action of nifedipine appear modified by the systemic hypote receptor activation of autonomic re intravenous nifedipine consisten chronotropic and inotropic respons the positive chronotropic response attenuated, but not completely ab sistent with recent data in consci strumented animals.[6] Experimenta that because of its potential memb tion, propranolol may reduce baro

Thus, the decrease in MVO_2 a ministration appears to be relatec heart rate response and to the sus afterload resulting from systemic tionally, a decrease in left ventricu

formance may contribute to the reduction in MVO_2. A depression of left ventricular contractile performance as assessed by left ventricular dP/dt max after nifedipine has been reported in patients who receive chronic β-blocker therapy.[26]

Clinical implications: This study demonstrates that in patients with CAD, nifedipine reduces MVO_2 after pretreatment with propranolol (Table III). The coronary arterial vasodilatory effect of nifedipine is maintained in the presence of β-receptor blockade, and a probable propranolol-induced inappropriate vasoconstriction may be offset by nifedipine. The combination of nifedipine and propranolol may be useful in treating patients with effort-induced angina when symptoms cannot be controlled by monotherapy. In contrast to other calcium channel blockers, nifedipine combined with β-receptor blockers does not induce detrimental effects on sinus node and atrioventricular node function.[27] However, the combination should be used carefully, because adverse effects have been observed occasionally, especially in patients with left ventricular dysfunction.[28–30]

Acknowledgment: We thank Bayer Pharmaceutical Company, West Germany, for supplying us with nifedipine solution. Sincere appreciation is also extended to Susanne Büx, Thea Dinauer and Annemarie Bosse for technical assistance.

Announces a major advance in the short-term management of heart failure

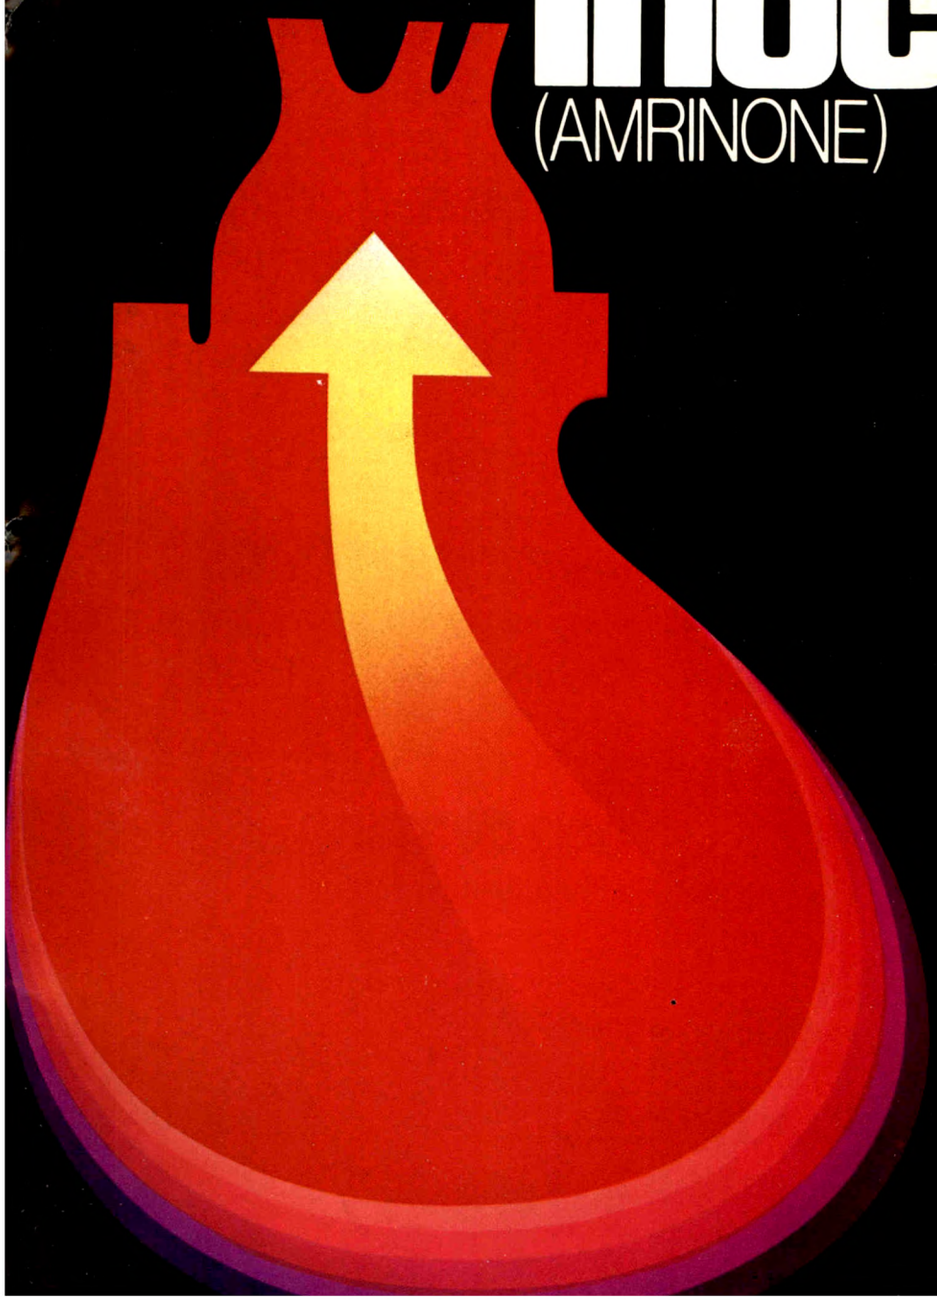
New

Inocor®

(AMRINONE)

I.V.

LACTAT
SOLUT



New **Inocor®** I.V.
(AMRINONE) LACTATE SOLUTION

a major advance that expands the limits of inotropic therapy

INOCOR provides distinctive inotropic action for the short-term management of heart failure in patients who have not responded adequately to digitalis, diuretics, and/or vasodilators

distinctive inotropic action...

- Rapidly increases cardiac output and lowers filling pressure*
- No significant change in heart rate or blood pressure*
- Vasodilating action reduces the strain on the failing heart
- Symptomatic relief can be expected following hemodynamic improvement
- Independent of the effects of digitalis or catecholamines

rapidly stabilizes the failing heart without adding to myocardial oxygen demand

- Improves the efficiency of the failing heart because myocardial oxygen demand is usually unchanged
- Intended for use in patients who can be closely monitored and do not respond adequately to prior therapy*

heart rate and blood pressure not significantly changed

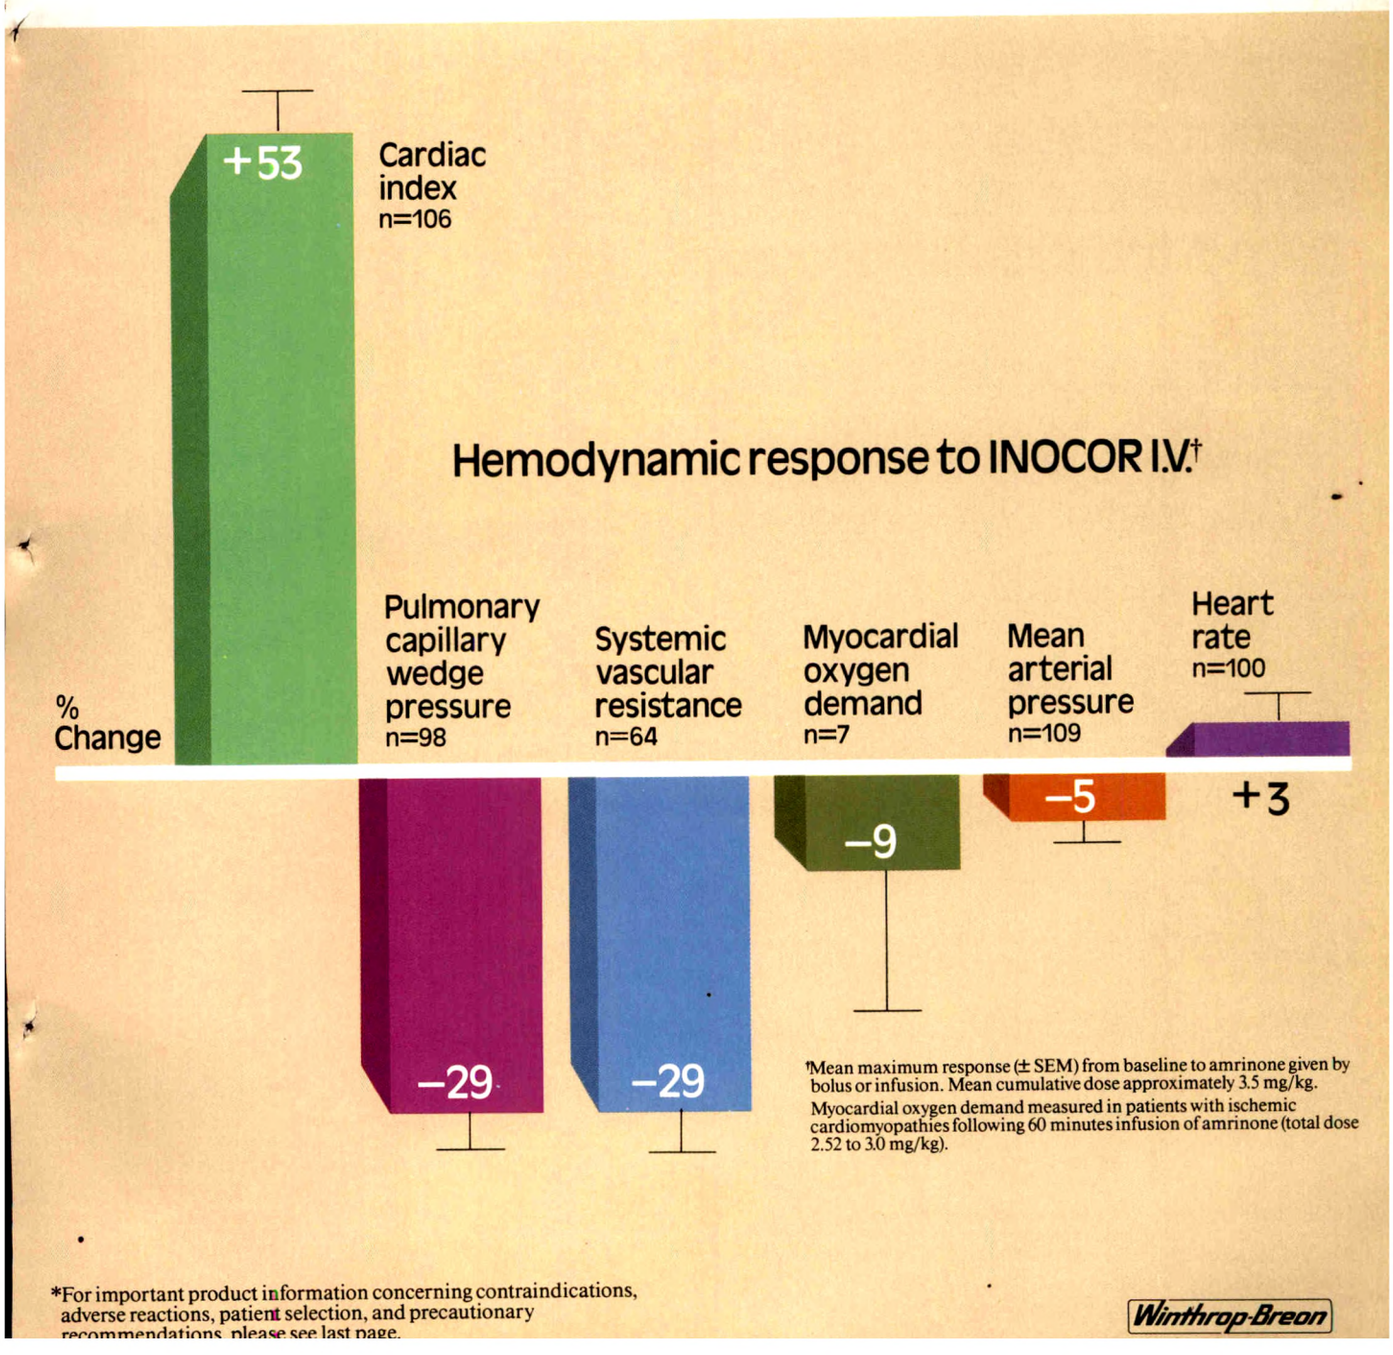
- Has not been shown to increase the risk of arrhythmias

New

Inocor® I.V.

(AMRINONE) LACTATE SOLUTION

a major advance that expands the limits of inotropic therapy



†Mean maximum response (± SEM) from baseline to amrinone given by bolus or infusion. Mean cumulative dose approximately 3.5 mg/kg.
Myocardial oxygen demand measured in patients with ischemic cardiomyopathies following 60 minutes infusion of amrinone (total dose 2.52 to 3.0 mg/kg).

Winthrop-Breon

New

Inocor® I.V.

(AMRINONE) LACTATE SOLUTION

a major advance that expands the limits of inotropic therapy

Symptomatic relief with INOCOR I.V. can be expected following hemodynamic improvement

Patient progress is reflected by:

- Increase in cardiac output
- Reduction in pulmonary capillary wedge pressure
- Improvement in clinical symptomatology
  - Dyspnea
  - Orthopnea
  - Paroxysmal nocturnal dyspnea
  - Fatigue

Benefits sustained during therapy

- No evidence of tachyphylaxis

For important product information concerning contraindications, adverse reactions, patient selection, and precautionary recommendations, please see last page.

- Patients receiving INOCOR should be carefully monitored with the following laboratory studies: platelet counts, liver enzymes, fluid and electrolyte changes, and renal function. Hypokalemia should be corrected by potassium supplementation in advance of or during amrinone use.
- In closely monitored clinical trials, patients with amrinone-related thrombocytopenia whose platelet counts were not allowed to remain depressed, showed no bleeding phenomena.
- Hepatotoxicity (liver enzyme alterations) has been observed following long term oral therapy. It has been observed, in a limited experience (0.2%), following intravenous administration of amrinone.
- While hypersensitivity has not been attributed to amrinone, this possibility should be considered with repeated administration.
- Until additional experience is available, concurrent administration with disopyramide should be undertaken with caution.

New

Inocor® I.V.

(AMRINONE) LACTATE SOLUTION

a major advance that expands the limits of inotropic therapy

How to use INOCOR

1. Initiate therapy with a 0.75 mg/kg bolus given slowly over 2 to 3 minutes.
2. Continue therapy with maintenance infusion between 5 and 10 μg/kg/min.
3. Based on clinical response, an additional bolus injection of 0.75 mg/kg may be given 30 minutes after the initiation of therapy.
4. The rate of infusion usually ranges from 5 to 10 μg/kg/min such that the recommended total daily dose (including boluses) does not exceed 10 mg/kg. A limited number of patients studied at higher doses support a dosage regimen up to 18 mg/kg/day for shortened durations of therapy.
5. The rate of administration and the duration of therapy should be adjusted according to the patient's response. The physician may wish to reduce or titrate the infusion downward based on clinical responsiveness or untoward effects.

- INOCOR may be administered as supplied or diluted in normal or half-normal saline to a concentration of 1 mg/mL to 3 mg/mL.
- INOCOR should not be diluted with solutions that contain dextrose (glucose).
- A chemical interaction occurs slowly over a 24-hour period when the intravenous solution of INOCOR is mixed directly with dextrose (glucose)-containing solutions.
- INOCOR may be injected into running dextrose (glucose) lines.
- All diluted solutions should be used within 24 hours.

New

Inocor® I.V.

(AMRINONE)

LACTATE SOLUTION

a major advance that expands the limits of inotropic therapy

- Hemodynamics rapidly improved
- Appropriate for hypertensive, normotensive, or hypotensive patients who have adequate filling pressure and those with myocardial ischemia
- Adverse reactions manageable and reversible
- Duration of therapy depends on patient responsiveness
- Dependable, controlled response with intravenous infusion
- Easy to administer

For important product information concerning contraindications, adverse reactions, patient selection, and precautionary recommendations, please see next page.

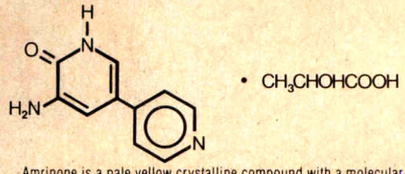
INOCOR® LACTATE INJECTION

Brand of amrinone lactate
Sterile Intravenous Solution

DESCRIPTION: INOCOR lactate injection, brand of amrinone lactate, represents a new class of cardiac inotropic agents distinct from digitalis glycosides or catecholamines. Amrinone lactate is designated chemically as 5-Amino [3,4′-bipyridin]-6(1*H*)-one lactate and has the following structure:



Amrinone is a pale yellow crystalline compound with a molecular weight of 187.2 and an empirical formula of $C_{10}H_9N_3O$. Each mole of lactic acid has a molecular weight of 90.08 and an empirical formula of $C_3H_6O_3$. The solubilities of amrinone at pH's 4.1, 6.0, and 8.0 are 25, 0.9, and 0.7 mg/mL, respectively.

INOCOR lactate injection is available as a sterile solution in 20 mL ampuls for intravenous administration. Each mL contains INOCOR lactate equivalent to 5 mg of base and 0.25 mg of sodium metabisulfite added as a preservative in Water for Injection. All dosages expressed in the package insert are expressed in terms of the base, amrinone. The pH is adjusted to between 3.2 to 4.0 with lactic acid or sodium hydroxide. The total concentration of lactic acid can vary between 5.0 mg/mL and 7.5 mg/mL.

CLINICAL PHARMACOLOGY: INOCOR lactate injection is a positive inotropic agent with vasodilator activity, different in structure and mode of action from either digitalis glycosides or catecholamines.

The mechanism of its inotropic and vasodilator effects has not been fully elucidated.

With respect to its inotropic effect, experimental evidence indicates that it is not a beta-adrenergic agonist. It inhibits myocardial cyclic adenosine monophosphate phosphodiesterase (c-AMP) activity and increases cellular levels of c-AMP. Unlike digitalis, it does not inhibit sodium-potassium adenosine triphosphatase activity.

With respect to its vasodilatory activity, INOCOR reduces afterload and preload by its direct relaxant effect on vascular smooth muscle.

Pharmacokinetics: Following intravenous bolus (1 to 2 minutes) injection of 0.68 mg/kg to 1.2 mg/kg to normal volunteers, INOCOR had a volume of distribution of 1.2 liters/kg; and following a distributive phase half-life of about 4.6 minutes in plasma, had a mean apparent first-order terminal elimination half-life of about 3.6 hours. In patients with congestive heart failure receiving infusions of INOCOR the mean apparent first-order terminal elimination half-life was about 5.8 hours.

Amrinone has been shown in one study to be 10% to 22% bound to human plasma protein by ultrafiltration in vitro, and in another study 35% to 49% bound by either ultrafiltration or equilibrium dialysis.

The primary route of excretion in man is *via* the urine as both amrinone and several metabolites (N-glycolyl, N-acetate, O-glucuronide and N-glucuronide). In normal volunteers, approximately 63% of an oral dose of ^{14}C-labelled amrinone was excreted in the urine over a 96-hour period. In the first 8 hours, 51% of the radioactivity in the urine was amrinone with 5% as the N-acetate, 8% as the N-glycolate, and less than 5% for each glucuronide. Approximately 18% of the administered dose was excreted in the feces in 72 hours.

In a 24-hour nonradioactive intravenous study, 10% to 40% of the dose was excreted in urine as unchanged amrinone with the N-acetyl metabolite representing less than 2% of the dose.

In congestive heart failure patients, after a loading bolus dose, steady-state plasma levels of about 2.4 μg/mL were able to be maintained by an infusion of 5 μg/kg/min to 10 μg/kg/min. In some congestive heart failure patients, with associated compromised renal and hepatic perfusion, it is possible that plasma levels of amrinone may rise during the infusion period; therefore, in these patients, it may be necessary to monitor the hemodynamic response and/or drug level. The principal measures of patient response include cardiac index, pulmonary capillary wedge pressure, central venous pressure, and their relationship to plasma concentrations. Additionally, measurements of blood pressure, urine output, and body weight may prove useful, as may such clinical symptoms as orthopnea, dyspnea, and fatigue.

Pharmacodynamics: In patients with depressed myocardial function, INOCOR lactate injection produces a prompt increase in cardiac output due to its inotropic and vasodilator actions.

Following a single intravenous bolus dose of INOCOR of 0.75 mg/kg to 3 mg/kg in patients with congestive heart failure, dose-related maximum increases in cardiac output occur (of about 28% at 0.75 mg/kg to about 61% at 3 mg/kg). The peak effect occurs within 10 minutes at all doses. The duration of effect depends upon dose, lasting about 1/2 hour at 0.75 mg/kg and approximately 2 hours at 3 mg/kg.

Over the same range of doses, pulmonary capillary wedge pressure and total peripheral resistance show dose-related decreases (mean maximum decreases of 29% in pulmonary capillary wedge pressure and 33% in systemic vascular resistance). At doses up to 3.0 mg/kg dose-related decreases in diastolic pressure (up to 13%) have been observed. Mean arterial pressure decreases (9.7%) at a dose of 3.0 mg/kg. The heart rate is generally unchanged.

The changes in hemodynamic parameters are maintained during continuous intravenous infusion and for several hours thereafter.

INOCOR lactate injection is effective in fully digitalized patients without causing signs of cardiac glycoside toxicity. Its inotropic effects are additive to those of digitalis. In cases of atrial flutter/fibrillation, it is possible that INOCOR may increase ventricular response rate because of its slight enhancement of A/V conduction. In these cases, prior treatment with digitalis is recommended.

Improvement in left ventricular function and relief of congestive heart failure in patients with ischemic heart disease have been observed. The improvement has occurred without inducing symptoms or electrocardiographic signs of myocardial ischemia.

At constant heart rate and blood pressure, increases in cardiac output occur without measurable increases in myocardial oxygen consumption or changes in arterio-venous oxygen difference.

Inotropic activity is maintained following repeated intravenous doses of INOCOR. INOCOR administration produces hemodynamic and symptomatic benefits to patients not satisfactorily controlled by conventional therapy with diuretics and cardiac glycosides.

INDICATIONS AND USAGE: INOCOR lactate injection is indicated for the short-term management of congestive heart failure. Because of limited experience and potential for serious adverse effects (see ADVERSE REACTIONS), INOCOR should be used only in patients who can be closely monitored and who have not responded adequately to digitalis, diuretics, and/or vasodilators. Although most patients have been studied hemodynamically for periods only up to 24 hours, some patients were studied for longer periods and demonstrated consistent hemodynamic and clinical effects. The duration of therapy should depend on patient responsiveness.

CONTRAINDICATIONS: INOCOR lactate injection is contraindicated in patients who are hypersensitive to it.

It is also contraindicated in those patients known to be hypersensitive to bisulfites.

PRECAUTIONS: General: INOCOR lactate injection should not be used in patients with severe aortic or pulmonic valvular disease in lieu of surgical relief of the obstruction. Like other inotropic agents, it may aggravate outflow tract obstruction in hypertrophic subaortic stenosis.

During intravenous therapy with INOCOR lactate injection, blood pressure and heart rate should be monitored and the rate of infusion slowed or stopped in patients showing excessive decreases in blood pressure.

Patients who have received vigorous diuretic therapy may have insufficient cardiac filling pressure to respond adequately to INOCOR lactate injection, in which case cautious liberalization of fluid and electrolyte intake may be indicated.

Supraventricular and ventricular arrhythmias have been observed in the very high-risk population treated. While amrinone per se has not been shown to be arrhythmogenic, the potential for arrhythmia, present in congestive heart failure itself, may be increased by any drug or combination of drugs.

Thrombocytopenia and hepatotoxicity have been noted (see ADVERSE REACTIONS).

USE IN ACUTE MYOCARDIAL INFARCTION: No clinical trials have been carried out in patients in the acute phase of postmyocardial infarction. Therefore, INOCOR lactate injection is not recommended in these cases.

Laboratory Tests: Fluid and Electrolytes: Fluid and electrolyte changes and renal function should be carefully monitored during amrinone lactate therapy. Improvement in cardiac output with resultant diuresis may necessitate a reduction in the dose of diuretic. Potassium loss due to excessive diuresis may predispose digitalized patients to arrhythmias. Therefore, hypokalemia should be corrected by potassium supplementation in advance of or during amrinone use.

Drug Interactions: In a relatively limited experience, no untoward clinical manifestations have been observed in patients in which INOCOR lactate injection was used concurrently with the following drugs: digitalis glycosides; lidocaine, quinidine; metoprolol, propranolol; hydralazine, prazosin; isosorbide dinitrate, nitroglycerine; chlorthalidone, ethacrynic acid, furosemide, hydrochlorothiazide, spironolactone, captopril; heparin, warfarin; potassium supplements; insulin; diazepam.

One case report of excessive hypotension has been reported when amrinone was used concurrently with disopyramide.

Until additional experience is available, concurrent administration with NORPACE® (disopyramide) should be undertaken with caution.

Carcinogenesis, Mutagenesis, Impairment of Fertility: The 1-year interim evaluation of the 2-year oral carcinogenicity study on F344 rats indicated no tumor induction at that time.

The mouse micronucleus test (at 7.5 to 10 times the maximum human dose) and the Chinese hamster ovary chromosome aberration assay were positive indicating both clastogenic potential and suppression of the number of polychromatic erythrocytes. However, the Ames Salmonella assay, mouse lymphoma study, and cultured human lymphocyte metaphase analysis were all negative. The clastogenic effects are in contrast to negative results obtained in the rat male and female fertility studies, and a three-generation study in rats, both with oral dosing.

Slight prolongation of the rat gestation period was seen in these studies at dose levels of 50 mg/kg/day and 100 mg/kg/day. Dystocia occurred in dams receiving 100 mg/kg/day resulting in increased numbers of stillbirths, decreased litter size, and poor pup survival.

Pregnancy Category C: In New Zealand white rabbits, amrinone has been shown to produce fetal skeletal and gross external malformations at oral doses of 16 mg/kg and 50 mg/kg which were toxic for the rabbit. Studies in French Hy/Cr rabbits using oral doses up to 32 mg/kg/day did not confirm this finding. No malformations were seen in rats receiving amrinone intravenously at the maximum dose used, 15 mg/kg/day (approximately the recommended daily intravenous dose for patients with congestive heart failure). There are no adequate and well-controlled studies in pregnant women. Amrinone should be used during pregnancy only if the potential benefit justifies the potential risk to the fetus.

Nursing Mothers: Caution should be exercised when amrinone is administered to nursing women, since it is not known whether it is excreted in human milk.

Pediatric Use: Safety and effectiveness in children have not been established.

ADVERSE REACTIONS: Thrombocytopenia: Intravenous INOCOR lactate injection resulted in platelet count reductions to below 100,000/mm³ or normal limits in 2.4 percent of the patients.

It is more common in patients receiving prolonged therapy. To date, in closely-monitored clinical trials, in patients whose platelet counts were not allowed to remain depressed, no bleeding phenomena have been observed.

Platelet reduction is dose dependent and appears due to a decrease in platelet survival time. Several patients who developed thrombocytopenia while receiving amrinone had bone marrow examinations which were normal. There is no evidence relating platelet reduction to immune response or to a platelet activating factor.

Gastrointestinal Effects: Gastrointestinal adverse reactions reported with INOCOR lactate injection during clinical use included nausea (1.7%), vomiting (0.9%), abdominal pain (0.4%), and anorexia (0.4%).

Cardiovascular Effects: Cardiovascular adverse reactions reported with INOCOR lactate injection include arrhythmia (3%) and hypotension (1.3%).

Hepatic Toxicity: In dogs, at IV doses between 9 mg/kg/day and 32 mg/kg/day, amrinone showed dose-related hepatotoxicity manifested either as enzyme elevation or hepatic cell necrosis or both. Hepatotoxicity has been observed in man following long-term oral dosing and has been observed, in a limited experience (0.2%), following intravenous administration of amrinone.

Hypersensitivity: There have been reports of several apparent hypersensitivity reactions in patients treated with oral amrinone for about two weeks. Signs and symptoms were variable but included pericarditis, pleuritis and ascites (1 case), myositis with interstitial shadowing on chest x-ray and elevated sedimentation rate (1 case) and vasculitis with nodular pulmonary densities, hypoxemia, and jaundice (1 case). The first patient died, not necessarily of the possible reaction, while the last two resolved with discontinuation of therapy. None of the cases were rechallenged so that attribution to amrinone is not certain, but possible hypersensitivity reactions should be considered in any patient maintained for a prolonged period on amrinone.

General: Additional adverse reactions observed in intravenous amrinone clinical studies include fever (0.9%), chest pain (0.2%), and burning at the site of injection (0.2%).

Management of Adverse Reactions: Platelet Count Reductions: Asymptomatic platelet count reduction (to <150,000/mm³) may be reversed within one week of a decrease in drug dosage. Further, with no change in drug dosage, the count may stabilize at lower than pre-drug levels without any clinical sequelae. Pre-drug platelet counts and frequent platelet counts during therapy are recommended to assist in decisions regarding dosage modifications.

Should a platelet count less than 150,000/mm³ occur, the following actions may be considered:

- Maintain total daily dose unchanged, since in some cases counts have either stabilized or returned to pre-treatment levels.
- Decrease total daily dose.
- Discontinue amrinone if, in the clinical judgment of the physician, risk exceeds the potential benefit.

Gastrointestinal Side Effects: While gastrointestinal side effects were seen infrequently with intravenous therapy, should severe or debilitating ones occur, the physician may wish to reduce dosage or discontinue the drug based on the usual benefit-to-risk considerations.

Hepatic Toxicity: In clinical experience to date with intravenous administration, hepatotoxicity has been observed rarely. If acute marked alterations in liver enzymes occur together with clinical symptoms suggesting an idiosyncratic hypersensitivity reaction, amrinone therapy should be promptly discontinued.

If less than marked enzyme alterations occur without clinical symptoms, these nonspecific changes should be evaluated on an individual basis. The clinician may wish to continue amrinone, reduce dosage, or discontinue the drug based on the usual benefit/risk considerations.

OVERDOSAGE: Doses of INOCOR lactate injection may produce hypotension because of its vasodilator effect. If this occurs, amrinone administration should be reduced or discontinued. No specific antidote is known, but general measures for circulatory support should be taken.

In rats, the LD_{50} of amrinone, as the lactate salt, was 102 mg/kg or 130 mg/kg intravenously in two different studies and 132 mg/kg orally (intragastrically); as a suspension in aqueous gum tragacanth the oral LD_{50} was 239 mg/kg.

DOSAGE AND ADMINISTRATION: INOCOR lactate injection may be administered as supplied or diluted in normal, or half normal saline solution to a concentration of 1 mg/mL to 3 mg/mL. Diluted solutions should be used within 24 hours.

INOCOR lactate injection may be injected into running dextrose (glucose) infusions through a Y-Connector or directly into the tubing where preferable.

A chemical interaction occurs slowly over a 24-hour period when the intravenous solution of INOCOR lactate injection is mixed directly with dextrose (glucose)-containing solutions. **THEREFORE, INOCOR LACTATE INJECTION SHOULD NOT BE DILUTED WITH SOLUTIONS THAT CONTAIN DEXTROSE (GLUCOSE) PRIOR TO INJECTION.**

The following procedure is recommended for the administration of INOCOR lactate injection:

1. Initiate therapy with a 0.75 mg/kg bolus given slowly over 2 to 3 minutes.
2. Continue therapy with a maintenance infusion between 5 μg/kg/min and 10 μg/kg/min.
3. Based on clinical response, an additional bolus injection of 0.75 mg/kg may be given 30 minutes after the initiation of therapy.
4. The rate of infusion usually ranges from 5 μg/kg/min to 10 μg/kg/min such that the recommended total daily dose (including boluses) does not exceed 10 mg/kg. A limited number of patients studied at higher doses support a dosage regimen up to 18 mg/kg/day for shortened durations of therapy.
5. The rate of administration and the duration of therapy should be adjusted according to the response of the patient. The physician may wish to reduce or titrate the infusion downward based on clinical responsiveness or untoward effects.

The above dosing regimens can be expected to place most patient's plasma concentration of amrinone at approximately 3 μg/mL. Increases in cardiac index show a linear relationship to plasma concentration of a range of 0.5 μg/mL to 7 μg/mL. No observations have been made at greater plasma concentrations.

Patient improvement may be reflected by increases in cardiac output, reduction in pulmonary capillary wedge pressure, and such clinical responses as a lessening of dyspnea and an improvement in other symptoms of heart failure, such as orthopnea and fatigue.

Monitoring central venous pressure (CVP) may be valuable in the assessment of hypotension and fluid balance management. Prior correction or adjustment of fluid/electrolytes is essential to obtain satisfactory response with amrinone.

Parenteral drug products should be inspected visually and should not be used if particulate matter or discoloration is observed.

HOW SUPPLIED: Ampuls of 20 mL sterile, clear yellow solution containing INOCOR 5 mg/mL, box of 5 (NDC 0024-0888-20). Each 1 mL contains INOCOR lactate equivalent to 5 mg base and 0.25 mg sodium metabisulfite in Water for Injection. The pH of INOCOR lactate injection is adjusted to a range of 3.2 to 4.0 with lactic acid or sodium hydroxide.

Protect INOCOR lactate ampuls from light. Ampul packaging is light resistant for protection during storage.

Store at room temperature.

NOTE: Parenteral drug products should be inspected visually and should not be used if particulate matter or discoloration is observed.

RIGHT HEART FAILURE

An International, Multi-Disciplinary Symposium

April 11, 12, 13, 1985

at the Hyatt Regency Hotel · Phoenix, Arizona

The symposium, whose presentation will be published as a textbook entitled **"Right Heart Failure"**, will provide an unprecedented forum for discussion on the "other side of the heart." Presentations will focus on medical and surgical considerations pertaining to the right side of the heart and pulmonary circulations. Participants will be eligible to receive Category I C.M.E. credit.

INFECTIOUS COMPLICATIONS OF NEOPLASTIC DISEASE

Controversies in Management

Edited by Arthur E. Brown, MD, and Donald Armstrong, MD
0-914316-43-5, approx. 400 pp., Oct. 1984, $40.00 casebound

Derived from a symposium sponsored by the Infectious Disease Service, Department of Medicine and the Department of Pediatrics, Memorial Sloan-Kettering Cancer Center, New York City, and Cornell University Medical College, New York City, this book presents the latest thinking by international authorities, all of whom were invited to present findings in their area of expertise on the diagnosis, treatment, and prevention of various bacterial, fungal, viral, and parasitic infections presenting in patients with neoplastic disease.

This is not just another "proceedings" volume. Rather it is an edited work, with papers by investigators who submitted definitive preparations for publication. Furthermore, the authors take a strong position on their topics, ask probing questions and promote a stimulating forum of controversy.

The result is a concise, dynamic study that belongs in the professional library of every physician treating patients with neoplastic disease.

Value of Arm Exercise Testing in Detecting Coronary Artery Disease

GARY J. BALADY, MD, DONALD A. WEINER, MD, CAROLYN H. McCABE, BS, and THOMAS J. RYAN, MD

Alternative methods of exercise testing are needed for patients with vascular, orthopedic or neurologic conditions who cannot perform leg exercise. To determine the sensitivity of arm exercise in detecting coronary artery disease (CAD), 30 patients with angina pectoris performed both arm ergometry and treadmill testing before coronary angiography. All patients had at least 70% diameter reduction in 1 or more major coronary arteries. Ischemic ST depression ($\geq$1 mm) or angina occurred more frequently (86%, 26 patients) with leg exercise than with arm exercise (40%, 12 patients). There was no significant difference in peak rate-pressure product achieved with either test, although the peak oxygen consumption was greater during leg exercise than during arm exercise (18 vs 13 ml/kg/min, respectively, p <0.001). For concordantly positive tests, the oxygen consumption at onset of ischemia was significantly lower during arm testing than during leg testing (12 vs 17 ml/kg/min, respectively, p <0.001). There was no significant difference in heart rate during either test at onset ischemia. Thus, arm exercise testing is a reasonable, but not equivalent, alternative to leg exercise testing in patients who cannot perform leg exercise.

(Am J Cardiol 1985;55:37–39)

Exercise testing is a standard noninvasive method used in the evaluation and management of patients with suspected coronary heart disease (CAD).[1] Many conditions, such as neurologic, vascular or orthopedic impairment of the lower extremities, often preclude performing an adequate treadmill or bicycle test. Dynamic arm exercise testing may be a valuable alternative to leg exercise in such patients,[2–4] although the sensitivity of this method of stress testing in detecting CAD is unknown. The present study evaluates the sensitivity of arm exercise testing in patients with angiographically proved CAD and compares the physiologic responses of dynamic arm and leg exercise in 30 patients.

Methods

Study population: The study group consisted of 30 patients referred for diagnostic evaluation of suspected or known CAD who could undergo arm and leg exercise testing and coronary angiography. Clinical data recorded included age, sex, type and severity of chest pain according to the Canadian Cardiovascular Society classification[5] and history of myocardial infarction and medications used.

Testing: All patients underwent 2 maximal, symptom-limited, graded exercise tests using an arm ergometer and treadmill, performed in random fashion alternating between morning and afternoon periods to avoid diurnal variation in exercise tolerance, so that 14 (46%) of the patients performed arm ergometry initially. Treadmill testing was performed using a Marquette Series 1800 treadmill electronically programmed according to the Bruce protocol.[6] The patients performed arm ergometry using a Quinton imaging table with an electronically braked bicycle ergometer, which was modified for arm exercise with replacement of the pedals with rubber handles. The patients were seated upright, with feet flat on the ground and the fulcrum of the handle was adjusted to shoulder height. They performed arm exercise initially at a workload of 35 W and continued at incremental workloads of 25 W every 3 minutes until the test was terminated.

A 12-lead electrocardiogram and blood pressure were recorded for both tests at rest, at 3-minute intervals during exercise, at peak exercise, and during recovery for at least 10 minutes. The blood pressure during arm exercise was measured with the patient dropping 1 arm to allow measurement, while arm cranking was continued with the other arm. Blood pressure recordings usually took no more than 20 seconds. The endpoints of both exercise tests were the development of either moderately severe angina pectoris, dyspnea, fatigue, complex ventricular arrhythmias or more than 3 mm of ST-segment depression on the monitoring electrocardiogram. An ischemic ST-segment response was defined as either 1 mm or

From the Evans Memorial Department of Clinical Research and The Department of Medicine, University Hospital, Boston University Medical Center, Boston, Massachusetts. Manuscript received June 18, 1984; revised manuscript received August 16, 1984, accepted August 20, 1984.

TABLE I Characteristics of Exercise Test Response

	Arm (n = 30)	Leg (n = 30)
Heart rate (beats/min)		
Rest	60 ± 11	63 ± 13
Peak	101 ± 18*	109 ± 17
Systolic blood pressure (mm Hg)		
Rest	128 ± 17	125 ± 18
Peak	161 ± 20	152 ± 22
Peak rate-pressure product (bpm × mm Hg × 10^3)	16 ± 4	16 ± 4
Peak VO_2 (ml/kg/min)	13 ± 5†	18 ± 1

* $p < 0.01$; † $p < 0.001$.
VO_2 = oxygen consumption.

more of horizontal or downsloping ST-segment depression or 1.5 mm of upsloping ST-segment depression from the isoelectric baseline that lasted at least 80 ms after the J point, for 3 consecutive beats during exercise or recovery. Exercise variables analyzed included the presence, magnitude and configurations of ST-segment depression; heart rate and oxygen consumption at onset of angina and ST depression; changes in heart rate and systolic blood pressure from rest to peak exercise; maximal heart rate and systolic blood pressure achieved, and their product; and peak oxygen consumption.

A Beckman metabolic cart comprising a volume transducer, a Beckman OM-11 oxygen analyzer, and a Beckman VO_2 carbon dioxide analyzer was used to determine minute oxygen consumption and minute carbon dioxide production. Oxygen and carbon dioxide concentrations in expired air were delivered through a mouthpiece, equipped with a low-resistance 3-way valve to a mixing chamber, volume transducer and gas analyzer.

Selective coronary arteriography used the brachial[7] or percutaneous femoral techniques,[8] and cineangiograms were recorded in multiple projections. Significant CAD was defined as at least 70% diameter narrowing of 1 or more major coronary arteries.

Statistical analysis: Comparisons of patient data were performed using chi-square analysis or the paired *t* test. Differences with probability values ($p < 0.05$) were considered to be statistically significant. Statistical methods were those outlined by Colton.[9]

Results

Population: The patient population consisted of 29 men and 1 woman, mean age 59 ± 9 years (range 40 to 71). All patients gave a history of exertional angina and 11 had class III or IV symptoms. A documented previous myocardial infarction was found in 12 patients (40%). Medications taken at the time of testing included β-adrenergic receptor blocking agents in 27 patients (90%) and calcium channel antagonists in 19 (64%). No patient was taking digitalis and no patient had either left ventricular hypertrophy or left bundle branch block on the electrocardiogram at rest. At cardiac catheterization, all patients had significant CAD: 8 (27%) had 1-vessel CAD, 9 (30%) had 2-vessel CAD, 11 (35%) had 3-vessel CAD, and 2 (8%) had left main CAD.

Exercise responses: Responses to both arm and leg exercise tests are listed in Tables I and II. Endpoints of exercise were moderate angina (20% during arm, 47% during leg) and fatigue (80% during arm, 53% during leg). The same endpoint for exercise during arm and leg testing was reached in 73% (22 of 30) of paired tests performed. Ischemic responses—angina or ST-segment depression (Fig. 1)—were demonstrated in 26 patients (86%) during leg exercise, and in 12 patients (40%) during arm exercise, despite a similar peak rate-pressure product during both tests. There was, however, a small difference in the peak heart rate attained during leg testing compared with arm testing (109 ± 17 vs 101 ± 8 beats/min, respectively, $p < 0.01$). Peak oxygen consumption during arm exercise was significantly less than that during leg exercise (13 vs 18 ml/kg/min, respectively, $p < 0.001$). Twelve patients (47%) had ischemic responses during both arm and leg exercise tests. There was no significant difference between the heart rate at the onset of angina (89 beats/min for arm exercise and 97 beats/min for leg exercise) or at the onset of ST-segment depression (99 beats/min for arm exercise vs 102 beats/min for leg exercise). However, measured oxygen consumption was higher for leg exercise than for arm exercise both at the onset of angina and at the onset of ST-segment depression (Fig. 2).

TABLE II Positive Tests Stratified By Extent of Coronary Artery Disease

No. of Diseased Vessels	No. of Pts.	Arm Test	Leg Test
1	8	3 (38%)	5 (62%)
2	9	5 (56%)	9 (100%)
3	11	3 (27%)	7 (64%)
Left main	2	1 (50%)	1 (50%)

Discussion

The results of this study demonstrate that important differences exist between dynamic arm and leg exercise, which are reflected in the exercise test response. Arm exercise testing was less sensitive than leg exercise testing in detecting CAD. Despite differences in the ischemic response, peak rate-pressure product for arm and leg exercise were not significantly different, although peak oxygen consumption for arm exercise was less than that for leg exercise.

Other investigators have examined the ischemic response to arm exercise in varying detail, and have had

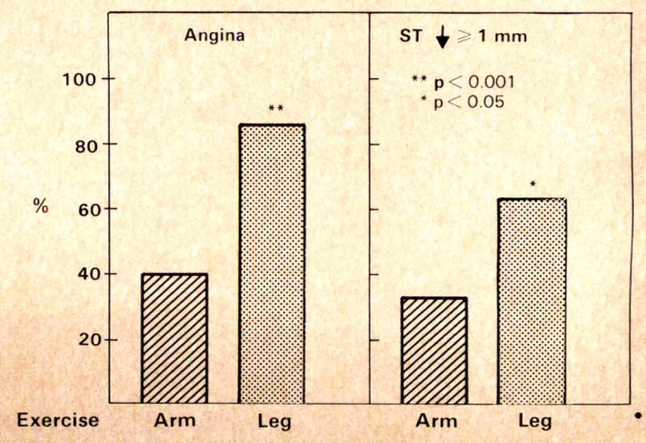

FIGURE 1. Ischemic responses to exercise.

conflicting results. Clausen and Trap-Jensen[10] studied 29 patients with angina who did not undergo cardiac catheterization. They found concordantly positive tests for angina in 11 of 12 patients who did both arm and leg exercise, although the rate-pressure product threshold for angina during arm exercise was greater than that of leg exercise. However, the ST-segment response during exercise was not examined. DeBusk et al,[11] in a study of 40 men who had previous myocardial infarctions, examined the ischemic response to arm and leg ergometry. The sensitivity of detecting CAD in this population was low for both tests (18% for arm vs 25% for leg, difference not significant). There was no difference in the peak rate-pressure product for each test. The sensitivities reported herein were probably remarkably low for both tests, because all subjects being tested had had a previous myocardial infarction and may not have had active ischemia. Schwade et al[3] also noted no difference in the sensitivity of arm compared with leg exercise in detecting CAD in a population of 33 men, although the extent of CAD and presence of angina were not defined in that population. In a study of 21 patients, Shaw et al[2] also found no difference in the ischemic response to arm ergometry vs treadmill testing. However, since all patients did not undergo cardiac catheterization to determine the extent of CAD, the actual sensitivities of either test could not be determined.

The physiologic responses to arm and leg dynamic exercise have been reported previously in several studies.[2–4,10–12] All studies have noted that the peak workload for arm exercise is significantly less than that of leg exercise. This is not surprising, considering the smaller muscle mass of upper extremities compared with lower extremities. The heart rate, systolic blood pressure, and rate-pressure product were higher for a given workload during arm exercise compared with leg exercise. This may be due to an increased sympathetic tone during arm exercise compared with leg exercise. Also, there is less vasodilation during arm work because of the relatively small mass of exercising muscle, and this could account for a higher peripheral resistance and, therefore, a greater blood pressure during arm exercise at any given amount of work. Our data suggest that changes in rate-pressure product at peak exercise did not reflect total myocardial oxygen consumption, since we found no significant difference in the rate-pressure product during peak arm and leg exercise despite a significant difference in ischemic response. Other determinants of myocardial oxygen consumption include myocardial contractility and the level of myocardial wall tension.[13] Wall tension could be substantially greater during leg exercise due to augmented venous return from the larger contracting muscles, leading to an increased left ventricular end-diastolic volume, as compared with upper-extremity exercise. Alternatively, vasodilatation of a greater number of resistance vessels during leg exercise, which leads to an overall decrease in peripheral resistance, may result in a net lowering of wall tension. Contractility may also be greater during leg exercise due to increases in left ventricular end-diastolic volume, or due to increased sympathetic stimulation of the myocardium. The use of radionuclide ventriculography or echocardiography may help to resolve these differences.

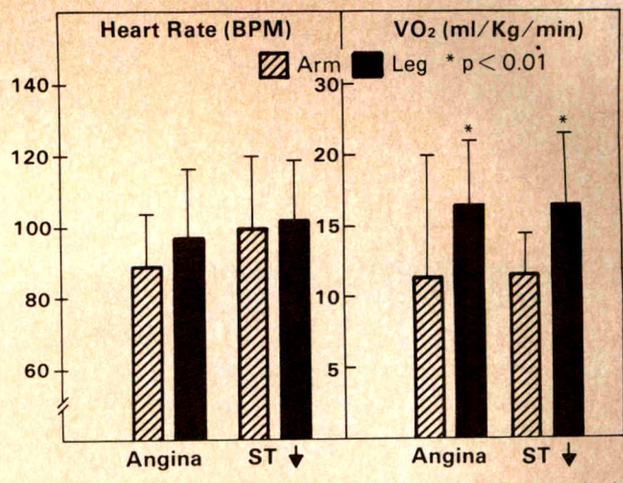

FIGURE 2. Exercise variables at the onset of ischemia for concordantly positive tests. VO_2 = oxygen consumption.

Some limitations of our study protocol should be considered. The patients continued to take their antianginal medications throughout the test period. Although the use of paired testing should negate medication effect, the medications could alter the physiologic responses to arm and leg exercise differently. Second, the patients were more familiar and facile with upright walking exercise than with arm cranking exercise, and this may also account for some degree of difference in the observed sensitivities. However, all patients did achieve similar peak rate-pressure products in both tests. Finally, the peak systolic blood pressure might be more subject to error during arm exercise testing because of technical problems.

Coronary Risk Factors and Their Pathway of Action Through Coronary Raised Lesions, Coronary Stenoses and Coronary Death

Multivariate Statistical Analysis of an Autopsy Series: The Oslo Study

INGAR HOLME, PhD, LARS A. SOLBERG, MD, LISA WEISSFELD, PhD, ANDERS HELGELAND, MD, INGVAR HJERMANN, MD, PAUL LEREN, MD, JACK P. STRONG, MD, and O. DALE WILLIAMS, PhD

From 1972 to 1973, 16,202 Oslo men, aged 40 to 49 years, were examined for cardiovascular disease and coronary heart disease (CHD) risk factors. This report describes the results of autopsy examinations from 204 of 471 men who died in this cohort with regard to associations between selected risk factors and (1) raised coronary atherosclerotic lesions (RL), (2) coronary artery stenosis, and (3) CHD death. Total serum cholesterol and blood pressure levels were positively associated with all 3 measures of coronary atherosclerosis and its complications, both in univariate and multivariate analyses, whereas high-density lipoprotein (HDL) cholesterol was highly and inversely related. Triglyceride levels, cigarette smoking, social class and physical activity at work and at leisure were not significantly associated with either of the 3 measures. When RL was added to the model with stenosis as the dependent variable, the risk factors no longer appeared as independent; this is consistent with the hypothesis that these factors, when significant, work through the development of RL to produce stenosis. HDL cholesterol was the only risk factor independently and significantly associated with CHD death when RL or stenosis or both were put into the model for CHD. This points to the possibility of HDL cholesterol also working through mechanisms other than the prevention of RL and stenosis toward CHD death.

(Am J Cardiol 1985;55:40–47)

The associations between coronary risk factors and clinically manifest coronary heart disease (CHD) have been established in numerous studies. The pathway of action has been hypothesized as being through the building of coronary atherosclerotic raised lesions (RL) and stenosis, finally resulting in occlusion, ischemia and myocardial infarction, angina pectoris or sudden death due to CHD. Many coronary risk factors are also known to be associated with RL. However, for some factors, such as cigarette smoking and physical activity at leisure, the associations are weaker or less consistent than those found in most clinical data.[1–5] Total serum cholesterol and blood pressure have consistently been associated with CHD in autopsy and clinical studies.[1–5] One study has also shown that high-density lipoprotein cholesterol (HDL-C) is inversely and strongly related to coronary RL.[2]

The number of coronary arteries with stenosis is a factor predictive of subsequent CHD, evaluated either angiographically or by autopsy.[6–9] Thus, risk factors for stenosis are also of interest. Associations between risk factors and RL similar to those between risk factors and

stenosis are presented herein. This study is an assessment of the importance of risk factors with respect to stenosis in addition to that of coronary RL, the hypothesis being that the impact of risk factors on stenoses is mediated through RL.

Methods

The Oslo Study has been described elsewhere.[10] In short, all Oslo men aged 40 to 49 years in 1972 were invited to a screening examination for assessment of cardiovascular risk (65% attendance proportion). The examination included blood pressure measurements and blood samples (nonfasting) for lipid analyses. Information on known cardiovascular disease or diabetes, physical activity both at work and at leisure and current and previous smoking habits was collected. HDL-C was derived from frozen specimens later in the study for 88% of the available autopsy series.[11]

The grading of atherosclerosis in the coronary arteries has been described elsewhere.[12] Briefly, coronary arteries were opened longitudinally and stenosis was defined as present whenever a reduction of the luminal diameter in an artery was more than 40% (judged visually). This evaluation was done for each of the 3 major coronary arterial branches. Coronary atherosclerotic raised lesions (i.e., the sum of fibrous plaques, complicated and calcified lesions), were graded by a specially trained team of pathologists at the Department of Pathology, Louisiana State University, New Orleans, who had no clinical or risk factor information about the cases.

A CHD death was recorded whenever 1 of 3 events happened: sudden death with or without thrombotic coronary occlusion but with severe stenosed coronary atherosclerosis, recent morphologic myocardial infarction, and myocardial scars after previous myocardial infarction.

This autopsy series is a selection of 204 consecutive cases gathered from the start of the study until January 1, 1981, at the Department of Pathology, Ullevaal Hospital, out of the total cohort of 16,202 men who attended the screening.

Statistical methods: In Table I the dependent variables of the study are defined. A raised lesion is measured by a percentage, whereas CHD is defined as being present or absent. Stenosis as a dependent variable is treated in several ways. In 1 analysis, the variable "Sten" is analyzed by an ordinal logistic regression model with possibly different intercepts, but common regression coefficients in each group of stenosis for all independent variables. In another, each of the variables, Sten 1, 2 and 3 was analyzed separately in relation to the independent variables to examine lack of homogeneity in the regression coefficients for increasing severity of stenosis. However, here some parts (Table I) of the data set had to be deleted to use the dichotomous logistic regression model. The independent variables were total serum cholesterol (CHOL), HDL-C, cholesterol ratio [HDL-C/(CHOL-HDL-C)], serum triglycerides, systolic and diastolic blood pressure, number of daily cigarettes, degree of physical activity at work and at leisure and social class.[13]

The strategy of analysis has been first to look for "outliers" and skewed distributions in all variables. All factors appeared to be fairly symmetric except triglycerides, which, after transformation to natural logarithm, ln(Trig), was approximately normal. The percentage of raised lesions was flat over the entire range, so some computations were done with the arcsine raised lesions transformation, but none of the conclusions changed. Results are therefore presented with untransformed raised lesions but with ln transformed triglycerides. No "outliers" were detected.

Systolic and diastolic blood pressure are highly correlated in this series and are entered only one at a time as independent variables in the multivariate analyses. HDL-C and the cholesterol ratio never entered simultaneously. This multicolinearity problem also appears with respect to total cholesterol and the cholesterol ratio. In the tables, only data for systolic blood pressure, total cholesterol and HDL-C are presented. Possible differences with regard to diastolic blood pressure or cholesterol ratio are mentioned.

TABLE I Definition of Dependent Variables in the Study

Variable	Definition
CHD	1 if CHD death; 0 otherwise
RL	Total percent involvement of the 3 main coronary arteries with raised lesions based on a separate classification for each of the 3 main arterial branches
Sten	Number of arteries involved with at least 1 stenosis (0, 1, 2, 3)
Sten 1	1 if any of the 3 coronary arteries is involved with at least 1 stenosis; 0 otherwise
Sten 2	1 if at least 2 of the coronary arteries are involved with at least 1 stenosis; 0 otherwise, excluding all men with 1 artery only involved with stenosis
Sten 3	1 if all 3 coronary arteries are involved with at least 1 stenosis; 0 otherwise, excluding all men with 1 or 2 arteries involved with stenosis

CHD = coronary heart disease; RL = raised lesions.

Raised lesions were analyzed by multiple linear regression model by fitting 10 arbitrarily chosen, separate sets of independent variables to RL. In the analysis of the 3 stenosis variables—Sten 1, Sten 2, Sten 3—the multiple logistic regression model was applied. For each of the 10 sets of variables (same as for raised lesions), the variable raised lesions were entered or deleted as an explanatory variable for stenoses. This addresses the question of whether it is likely that risk factors work through raised lesions in developing stenosis or if they have their own specific pathway of action different from building raised lesions. Ordinal logistic regression was performed with Sten as a dependent variable, allowing for different intercepts but with the same regression coefficient for each risk factor across the 4 stenosis groups.[14] In this way, all the data could be used.

In the final analysis of CHD, again the multiple logistic regression model was applied with the same set of risk factor models, with or without raised lesions or stenosis, using Sten as the conditioning variable. In a few analyses both raised lesions and stenoses were added to the risk factor set.

In this report, analyses have been presented for only the subset of the total cohort for which full information of all 10 risk factors was available. However, for models that involved HDL-C, analyses could be performed only on a subset of men. A few analyses were made in the so-called basal group, which consists of those who died from other than cardiovascular disease, with raised lesions and stenosis as dependent variables. Again, associations appeared to be more pronounced for factors that were already significant, but no new factor entered which could alter the main conclusions.

In the analysis with CHD death as the endpoint, some searches for interaction terms between raised lesions or stenosis and some risk factors were performed, but such multiplicative terms did not appear to be significant in any of the analyses.

Interaction terms between lipids and blood pressure were tested with raised lesions and stenosis as dependent variables. Some of the factors, such as CHD death, stenosis and social class, are discrete so that t tests for significant 0-order corre-

TABLE II Mean Values (± Standard Deviation) for Some Coronary Risk Factors in Autopsied and Nonautopsied Cases of Death from Start of Study Until December 31, 1980 (Autopsy Proportion: 35%)

Risk Factor*	Autopsy (n = 204)	Non-Autopsy (n = 378)	Total
Serum cholesterol (mg/dl)	288.6 ± 46.6	282.3 ± 58.6	284.5 ± 54.8
Triglycerides (mmol/l)	2.58 ± 1.46	2.51 ± 1.55	2.54 ± 1.52

lations cannot be interpreted as easily as in the continuous, normal case.

Results

Table II lists mean values of some selected risk factors in autopsied and nonautopsied cases among those who attended screening. There was a slight, nonsignificant excess risk present in the autopsied cases ($p > 0.10$).

Table III lists 0-order correlation coefficients between all dependent and independent variables together with mean values and standard deviations. The indicated high intercorrelation between the 3 dependent variables was expected and has been analyzed in more detail elsewhere.[9] None of the independent variables appear to be especially intercorrelated except diastolic and systolic blood pressure, HDL-C and the cholesterol ratio, and cholesterol and the cholesterol ratio.

Ten models were selected as being potentially interesting with regard to how groups of risk factors act on the various dependent variables. For each model, the variable raised lesions is added or deleted in the analyses with stenosis as the dependent variable. The same is repeated when CHD is the dependent variable, alternating also with stenosis as an independent variable.

In Table IV these 10 models for raised lesions are presented in terms of partial linear regression coefficients, their t values, and the R^2 values. Also in this extended data set, cigarette smoking could not be shown to be associated with coronary raised lesions, either marginally (Table III) or adjusted for social class or for serum cholesterol. Serum cholesterol level was highly significantly associated with raised lesions, as were HDL-C and systolic blood pressure. Systolic blood pressure associated significantly over and above that of cholesterol and HDL-C and the same was true for HDL-C, keeping the other 2 in the model. Finally, cholesterol added significantly to the predictive power when HDL-C and systolic blood pressure were already in the model.

Triglyceride levels [ln(Trig)] did not enter as a significant risk factor for raised lesions over and above that of the other lipid components. In the full regression model no risk factors other than cholesterol, HDL-C and systolic blood pressure contributed significantly to R^2, which remained unchanged when all other variables were added to these 3 factors. A search for interaction term for CHOL × SBP was negative and highly significant and that for SBP × HDL-C was of borderline significance (data not given). The R^2 was raised from 0.24 to 0.32 by the addition of CHOL × SBP in model 4.

The cholesterol ratio was also tested as an independent explanatory variable, but only gave somewhat increased explanatory power in relation to HDL-C alone, but not in relation to cholesterol and HDL-C when they were entered simultaneously as linear terms in the model (data not given).

Similar data for stenosis as the dependent variable are presented in Table V, given only for the Sten 1 variable. As with raised lesions, only cholesterol, HDL-C and systolic blood pressure were significant variables, with HDL-C and systolic blood pressure being less significant than serum cholesterol. Cigarette smoking was as poorly associated with stenosis as it was with raised lesions. No other variables even reached borderline significance. However, when the variable raised lesions was entered in the model, no risk factor was any longer significantly associated with stenosis. This was true whether adding 1 at a time, 2 at a time, or altogether, and this was consistent for all 3 stenosis variables (data not given).

One additional observation is that total and HDL-C tended to be more strongly associated with Sten 3 than with Sten 2, and again stronger with Sten 2 than with Sten 1, which is an indication that these risk factors become more important as predictors for the advanced stages of the stenosis process. The ordinal logistic regression, with Sten as dependent variable, assuming common regression coefficients for each factor across all stenosis groups, gave similar results, the only difference being that serum cholesterol increased its strength of association and systolic blood pressure became less significant (data not given).

Table VI is similar to the preceding tables, but involves CHD as the dependent variable. Again, exactly the same factors as mentioned above appeared as independent risk factors, that is, serum cholesterol, HDL-C and SBP, but SBP was less significant than before. None of the other variables entered into either the univariate or the multivariate analyses. Triglycerides appeared, however, as a factor of borderline significance in the multivariate analysis but with a negative

sign. If raised lesions or stenosis or both are forced into the model, HDL-C still appears as an inverse and significant risk factor working independently over and above that of all other factors (data not given). Figure 1 shows the association between percent CHD and HDL-C in 3 groups of raised lesions. The independent negative association is clearly indicated.

Both raised lesions and stenosis associate strongly with CHD, and each of them adds explanatory value to the other, with or without other risk factors present (data not given).

CHD is the endpoint most alike the endpoint used in clinical data with a living total cohort amenable for long-term follow-up. In most investigations, cigarette smoking is found to be highly and significantly associated with CHD incidence in prospective, population-based follow-up studies, and it has been especially stressed that the cigarette mediated risk of a CHD event increases as the severity (often measured by high levels of serum cholesterol or blood pressure or both) of atherosclerosis increases.[4,15] Therefore, the association between CHD and cigarette smoking has been explored

in different strata of raised lesions or stenoses to see if a tendency toward such an association could be traced. Figure 2 gives this relation for 3 subgroups of raised lesions, and in no groups are there tendencies towards a positive association between cigarette smoking and CHD. There are similar results for subgroups of stenoses (data not given).

Discussion

All inferences drawn from an autopsy series are contingent on the fact that everyone has died. With the autopsy information available, one of the consequences is that if a risk factor for CHD has the same strength with regard to other causes of death, the analysis of autopsy series will show no association with such factors to CHD, but may well show it in a population-based follow-up study. Causes of death are also more strongly competing against each other in this age group than in the living population. These limitations of autopsy findings must be considered when discussing similarities and differences between clinical and autopsy-based epidemiologic risk factor analyses that use CHD as the endpoint.

The degree of atherosclerosis as measured by raised lesions in this total autopsy material, consisting of 471 cases, was 44% in nonattendants and 48% in attendants ($p > 0.10$). This indicates a small selection difference with respect to coronary risk in the autopsy series. For those who attended with risk factor levels available, nonautopsied cases had a slightly but not significantly ($p > 0.10$) lower risk profile than autopsied cases. The proportion of CHD death among all deaths in the cohort

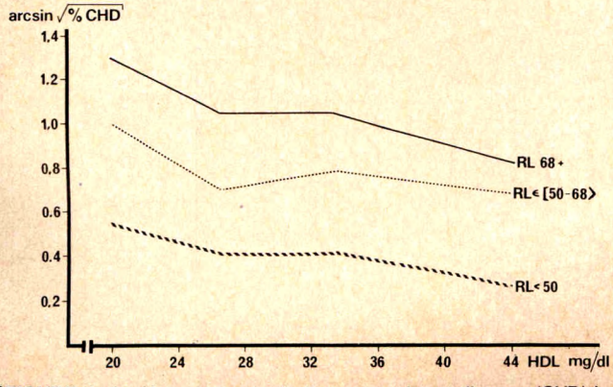

FIGURE 1. Arcsine square root of coronary heart disease (CHD) by high-density lipoprotein (HDL) cholesterol in 3 subgroups of coronary raised lesions (RL).

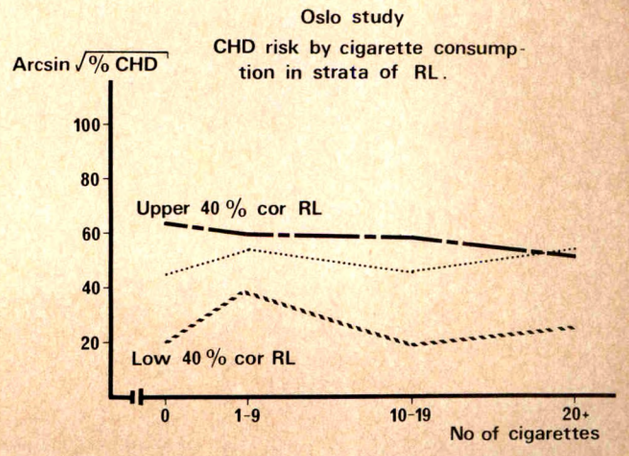

FIGURE 2. Arcsine square root × 100 of coronary heart disease (CHD) by cigarette smoking in 3 subgroups of coronary raised lesions (RL).

of all invited men to the Oslo Study was 36.4%, whereas in the autopsy series it was 38.2%. However, the CHD morbidity and mortality was 60% higher in the nonattending group than in the attending group during the first 5 years of follow-up.[5,16]

Serum cholesterol: The association between serum cholesterol and coronary raised lesions is highly significant both in univariate and multivariate analyses, as found in similar prospective autopsy studies among men.[17–20] The same association also applies for coronary stenosis, in univariate and in multivariate analyses, but when the variable raised lesions is entered into the multivariate model, serum cholesterol is no longer a significant risk factor. Analogously, serum cholesterol is also strongly associated with CHD death, both in univariate and in multivariate analyses, but when either raised lesions or stenosis are added to the model, serum cholesterol disappears as a risk factor. This finding is consistent with the hypothesis that cholesterol operates through establishment of raised lesions and by increasing the severity of stenosis and does not appear to influence other mechanisms of CHD death. These findings are in line with those from follow-up studies in the living population where serum cholesterol is a strong predictor for CHD morbidity and mortality.[5,16]

Blood pressure: The differences in associations between the dependent variables and the 2 blood pressure measurements were systematically small. With regard to raised lesions, systolic blood pressure was slightly more associated than diastolic, but for CHD diastolic blood pressure was somewhat more strongly associated. For stenosis the associations were of similar strength. Blood pressure was independently and significantly related to all 3 dependent variables, but most strongly to raised lesions. An association between blood pressure and raised lesions has been observed in some studies,[17,20] but not in others.[18,19] One reason why the association between blood pressure and CHD was only of borderline significance may be that blood pressure strongly relates to stroke which was included in the non-CHD death category, thus diluting the association. In addition, blood pressure seems to influence in a similar way CHD death as serum cholesterol, both being completely nonsignificant when raised lesions is entered into the models.

HDL cholesterol: This study is, to our knowledge, the first to demonstrate the systematic inverse relation between HDL-C and the 3 dependent variables both in univariate and multivariate analyses. This is more striking when it is realized that HDL-C measurements were done in frozen sera, with a reduction both in the mean and the dispersion by approximately 30%.[11] This finding is consistent with the clinical observation of HDL-C being an important acute atherogenic coronary risk factor[21–22] and supports the view that HDL-C may be operative at the formation level of atherosclerotic lesions. However, HDL-C was also a significant correlate to CHD, even after adjustments for raised lesions, stenosis and all the other independent variables. This result gives support to the theory that HDL-C may also influence other mechanisms that cause CHD death. A possible pathway of additional action would be through the association of HDL-C with factors that induce thrombi and spasm, but the literature is scarce with respect to a possible association between blood clotting factors and HDL-C. In the Oslo Study an inverse association between decreased fibrinolytic activity and triglycerides was shown,[23] but HDL-C was not evaluated in that study. The inverse association between triglycerides and HDL-C is well known,[24] so the question should be raised whether there exist associations between some blood clotting factors and HDL-C.

Another possible explanation is that HDL-C may be positively associated with alcohol consumption, which again could be negatively associated with CHD mortality in this population, but it is difficult to evaluate this explanation without alcohol consumption information, which was not available. However, 7 deaths were directly alcohol-related and these 7 men had a mean HDL-C level of 35.6 mg/dl (average 31.4).

Cigarette smoking: Cigarette smoking was not associated with any of the 3 dependent variables. For both raised lesions and stenosis, no tendency toward such an association was traced, either in univariate or in multivariate analyses, and this holds even within specific causes of death, such as cancer. Only the Honolulu study demonstrated an independent association between coronary raised lesions and cigarette smoking (restricting attention to prospective autopsy follow-up studies).[19] In neither the Malmo nor the Puerto Rico studies was such an association shown,[17,18] although for both studies a positive relation was shown between smoking and aortic atherosclerosis. This difference between the clinical and autopsy-based cigarette association to CHD could be explained by factors other than atherosclerotic lesions and stenoses. For instance, cigarette smoking may affect the myocardium and its conduction system,[25] it may interfere with the hematologic factors to enhance the formation of thrombi or spasm,[26] or cause fatal rhythm disturbances, thus more influencing complications to atherosclerosis. The relation between atherosclerosis in postmortem studies and cigarette smoking was recently reviewed.[27]

Clinical studies have shown that when atherosclerosis is advanced, cigarette smoking is an especially dangerous habit with respect to risk of CHD.[4,15] An attempt to investigate this hypothesis was made within this data set. When the data are grouped into 3 groups of raised lesions or in 4 groups of stenosis, one should expect the smoking factor to be negatively associated with CHD in the group of minor lesions or stenosis in which a predominance of non-CHD causes of death such as cancer is present. In the advanced raised lesions or stenosis group, however, the opposite should take place, with a clear positive tendency toward association between cigarette smoking and CHD. However, such a tendency could not be traced in these data where the lines of association were horizontal in all subgroups of raised lesions or stenosis (Fig. 2).

These findings are in contrast to what has been found in a similarly analyzed study of nonfatal myocardial infarction based on angiographically established coronary stenosis.[28] Also, selective biases may be present that tend to obscure the relation in the present data set.

Thus, the negative result for cigarette smoking in this study should be interpreted with care and can hardly be used as an argument against cigarette smoking as a deleterious factor in CHD.

Triglycerides: Triglyceride levels evaluated as ln(trig) was not a significant variable for raised lesions or stenosis in multivariate analysis. However, simple correlation coefficients of raised lesions and the 3 stenosis variables were technically significant ($p < 0.10$). With respect to raised lesions, this is in accordance with 1 study using univariate analysis,[19] but not with another.[18] Only the Honolulu study used multivariate analysis, and triglycerides did not appear to be significantly associated.[19] In the Oslo Study cohort follow-up, the triglyceride level was a significant positive risk factor for acute myocardial infarction even after adjustment for serum cholesterol.[15] This finding is not confirmed in the analysis of CHD against triglycerides in this study, even though the triglyceride level does not appear to be associated with other causes of death.

Social class and physical activity: Both social class and level of physical activity were far from being independent risk factors, even in univariate analyses. In the total cohort follow-up study, social class and physical activity at leisure were strongly related to CHD morbidity and mortality in univariate analysis. Physical activity at work was only of borderline significance (and was positively related to the outcome).[5,29] In a multivariate ecological analysis based on grouped data, only physical activity at leisure was of borderline significance for association with total mortality after adjustment for social class and coronary risk score (based on serum cholesterol, blood pressure and cigarette smoking).[29] Again, selection biases can not be ruled out as an explanation for the discrepancy with the clinical data.

Percutaneous Transluminal Coronary Angioplasty After Intracoronary Streptokinase in Evolving Acute Myocardial Infarction

SILVIO E. PAPAPIETRO, MD, WILLIAM A. H. MacLEAN, MD, ALFRED W. H. STANLEY, Jr., MD, RANDALL G. HESS, DO, NAN CORLEY, MD, JOAQUIN G. ARCINIEGAS, MD, and TERRY B. COOPER, MD

To achieve optimal myocardial revascularization and prevent rethrombosis of the infarct-related coronary artery, percutaneous transluminal coronary angioplasty (PTCA) was attempted in 18 patients with evolving acute myocardial infarction (9 anterior and 9 inferior) after administration of intracoronary streptokinase. PTCA was attempted 338 ± 151 minutes after the onset of symptoms. After thrombolytic therapy, 11 patients had a severe residual stenosis and 7 a persistent total occlusion of the infarct-related coronary artery. PTCA was successful in 13 of 18 patients: in 9 of 11 with coronary stenoses and in 4 of 7 with total coronary occlusions. PTCA reduced the severity of the coronary lesion from 91 ± 2% to 27 ± 7% ($p < 0.001$), and the transstenotic pressure gradient from 38 ± 5 to 6 ± 2 mm Hg ($p < 0.01$). One patient in cardiogenic shock died during urgent coronary surgery after unsuccessful PTCA. After PTCA, all patients received heparin and antiplatelet agents. One patient had reinfarction with reocclusion of the infarct-related artery 5 days after PTCA. The other 12 patients had an uneventful hospital course, and cardiac catheterization before hospital discharge (8 to 17 days) revealed reocclusion of the infarct-related coronary artery in 3 and persistent patency in 9. Persistent patency of the infarct-related artery was associated with preservation of left ventricular end-diastolic volume (initial 86 ± 6 ml/m², follow-up 91 ± 6 ml/m²), and improvement in left ventricular ejection fraction in some patients.

(Am J Cardiol 1985;55:48–53)

Thrombolysis with streptokinase (STK) early after the onset of acute myocardial infarction (AMI) frequently results in reestablishment of blood flow in thrombosed coronary arteries.[1–3] After thrombolysis, residual stenoses usually remain at the site of initial occlusion, and may result in incomplete revascularization and rethrombosis.[2,4,5] Anticoagulant and antiplatelet agents have been used to prevent rethrombosis, with variable success.[2–5] Coronary artery bypass surgery and percutaneous transluminal coronary angioplasty (PTCA) have been used immediately after or several days after thrombolysis to prevent reocclusion and achieve complete revascularization.[2–4] In this study, we report our experience with 18 patients with evolving transmural AMI in whom PTCA was attempted immediately after intracoronary STK treatment.

Methods

Patients: From October 1981, through December 1982, 83 patients with an evolving transmural AMI underwent cardiac catheterization and received intracoronary STK within 12 hours from onset of symptoms. The diagnosis of AMI was established by a history of chest pain, associated with more than 1.5 mm of ST-segment elevation in 2 or more electrocardiographic leads. Patients gave informed consent for cardiac catheterization, thrombolysis and PTCA. After administration of intracoronary STK, 18 patients (Table I) were selected for PTCA. They represent consecutive PTCA attempts, and were considered candidates for PTCA because after STK, they had a persistent occlusion or a severe stenosis in the infarct-related artery, jeopardizing a large segment of myocardium. The coronary lesion was believed suitable for

AMI = acute myocardial infarction; Ant = anterior; CAD = coronary artery disease; CI = cardiac index; Inf = inferior; LVEDP = left ventricular end-diastolic pressure; PTCA = percutaneous transluminal coronary angioplasty; V = vessel; + = present; 0 = absent.

PTCA based on its proximity to the ostium of the artery, type (discrete, concentric, noncalcified), presence and extent of residual thrombus and experience of the operator.

Cardiac catheterization: After initial evaluation, the 18 patients underwent cardiac catheterization (femoral approach). Cardiac output was determined by thermodilution. Biplane left ventricular angiography (30° right anterior oblique/15° cranial–60° left anterior oblique) was performed using 36 ml of diatrizoate meglumine injected over 3 seconds. Coronary angiography was performed in multiple views, and was performed first in the artery suspected not to be responsible for the AMI. Complete occlusion of the infarct-related artery was found in 16 patients and severe subtotal occlusion with nonocclusive thrombus was found in 2 (Table II).

Streptokinase: Patients received heparin, 10,000 IU, diphenhydramine hydrochloride, 50 mg, and methylprednisolone, 1.0 g intravenously, and nitroglycerin, 100 to 250 μg into the ostium of the infarct-related artery (left main or right coronary artery). No improvement in flow was observed after nitroglycerin. Subsequently, STK (Streptase,® Hoechst) 250,000 IU in 250 ml of 0.9 *M* sodium chloride, was administered as a 20,000-IU bolus in the infarct-related artery, and followed by an infusion of 4,000 or 8,000 IU/min, until the artery was recanalized or to a maximum of 400,000 IU. Coronary arteriograms were performed at regular intervals during STK administration. Recanalization was considered successful if flow was reestablished in a totally occluded vessel, or improved and the initial stenosis reduced in a subtotally occluded vessel. STK recanalization was successful in 9 patients with total occlusions and in the 2 with subtotal occlusions. In 7 patients STK recanalization was unsuccessful.

Angioplasty: Immediately after STK, PTCA[6] was attempted in the 18 patients. Movable guidewire angioplasty systems were not used. The mean time from onset of symptoms of AMI to PTCA was 338 ± 151 minutes (± standard deviation) (Table I). PTCA was considered successful when it resulted in recanalization and reestablishment of flow in a totally occluded artery, or an increase of more than 30% in the diameter of the lumen in a partially occluded artery. PTCA was attempted only in the infarct-related artery.

Management and follow-up: After PTCA, a No. 9Fr arterial sheath was left in the femoral artery for 12 to 16 hours while the patients were monitored in the coronary unit. Heparin, 1,000 to 1,500 IU/hour, was continuously infused to maintain the partial thromboplastin time 2 to 2½ times control for 3 to 5 days. All patients received dipyridamole or aspirin at least until follow-up cardiac catheterization. Oral anticoagulant treatment was not used routinely. Nitrates, calcium and β-blocking agents were used at the discretion of the attending physician. All patients with successful PTCA underwent follow-up cardiac catheterization before hospital discharge. Left ventricular volumes were derived from biplane left ventriculography.[7,8]

Statistical analysis: Data are reported as percentages and mean ± standard error of the mean. The significance of difference was assessed by paired *t* test (continuous variables) and by analysis of covariance (improvement in ejection fraction as dependent variable and collateral vessels time to reperfusion and late patency of the infarct artery as independent variables).

Results

Success and failure: PTCA was successful in 13 of 18 patients (72%): in 9 of 11 with a residual stenosis after thrombolytic therapy, and in 4 of 7 with persistent total coronary occlusions.

In the 4 patients with totally occluded arteries in whom PTCA was successful, the dilatation catheter was advanced through the occlusion site and anterograde flow documented by injection of contrast media. The balloon was usually inflated several times at this site until no significant transstenotic pressure gradient (mean less than 15 mm Hg) was present.

In the 13 patients with successful PTCA, the degree of coronary artery obstruction was reduced from 91 ± 2% to 27 ± 7% ($p < 0.001$) and the mean transstenotic pressure gradient from 38 ± 5 to 6 ± 2 mm Hg ($p < 0.01$). Figures 1 and 2 illustrate successful PTCA in 2 patients.

PTCA was unsuccessful in 5 of 18 patients (28%): in 3 patients a total occlusion could not be crossed and in 2 with residual stenoses it was associated with complications.

Collat. = collateral vessels; EDV = left ventricular end-diastolic volume; EF = left ventricular ejection fraction; ESV = left ventricular end-systolic volume; LAD = left anterior descending coronary artery; MI-CA = infarct-related coronary artery; PTCA = percutaneous transluminal coronary angioplasty; RCA = right coronary artery; S = successful; STK = streptokinase; U = unsuccessful; + = present; 0 = absent.

Complications and mortality: Two patients had complications related to PTCA. The first complication developed in a woman with an evolving anterolateral AMI (patient 5) associated right bundle branch block, recurrent ventricular tachycardia, and shock. After thrombolytic recanalization of the totally occluded left anterior descending artery, and as the dilatation catheter was being advanced across a residual 90% stenosis in the midsegment of the artery, ventricular fibrillation developed. Electrical cardioversion restored sinus rhythm and vital signs. Angiograms revealed patency of the artery, with no change in the midsegment stenosis and slow distal flow. The procedure was terminated, and urgent coronary bypass surgery was performed. The patient died in the operating room. She represents the only in-hospital death (1 of 18 patients or [5.5%]). The second complication occurred in a man with an evolving inferior AMI (patient 6) in whom the right coronary artery was recanalized with STK, leaving a severe 95% proximal stenosis. PTCA resulted in dissection and reocclusion of the right coronary artery. The patient had an otherwise uncomplicated hospital course.

Hospital course and follow-up: Hemorrhagic complications occurred in 5 patients. Two had recurrent bleeding with hematoma formation at the femoral puncture site, 1 had upper gastrointestinal bleeding, 1 had flank pain and hematuria, and 1 had a fall in hematocrit level during treatment with heparin. In all patients, bleeding resolved without consequences after heparin administration was discontinued.

Patient 3 had anterolateral reinfarction 5 days after successful PTCA of the left anterior descending coronary artery. Cardiac catheterization revealed reocclusion of the artery, and urgent coronary bypass surgery was performed without complication.

The remaining 12 patients with successful PTCA had a stable and uneventful hospital course and underwent follow-up cardiac catheterization and angiography at a mean of 12 days (range 8 to 17). The infarct-related artery was patent in 9 (75%). In these 9 patients, the residual stenosis present immediately after PTCA (25 ± 8%) was unchanged at follow-up study (31 ± 8%, difference not significant [NS]). Left ventricular angiography revealed no changes in left ventricular end-diastolic volume (initial 86 ± 6 ml/m², follow-up 91 ± 6 ml/m², NS), while left ventricular ejection fraction increased (>0.04) in 5, decreased (>0.04) in 3 and was unchanged in 1 patient. An increase in ejection fraction was always associated with an improvement in wall motion in the infarct zone. The 4 patients in whom left ventricular ejection fraction did not increase (patients 7, 9, 12 and 14) were receiving β-blocking agents at the time of follow-up cardiac catheterization. Compared with patients in whom left ventricular ejection fraction did not improve, those in whom it increased more frequently had collateral vessels to the distal portion of the occluded infarct-related artery ($p = 0.04$), a shorter time from onset of symptoms to PTCA ($p = 0.15$), and a patent infarct-related artery at follow-up angiography ($p = 0.04$).

In 3 patients (25%) the infarct-related artery had reoccluded. Review of the hospital course in these 3

patients (nos. 10, 17 and 18) did not reveal a clinical event (chest pain, ST-segment changes during electrocardiographic monitoring, frequent or sustained ventricular arrhythmias or paroxysmal dyspnea) that could have been temporally associated to rethrombosis.

Discussion

In patients with evolving AMI, thrombotic occlusion of the infarct-related artery is frequently demonstrated if angiographic studies are performed soon after the onset of symptoms.[9] Intracoronary STK can recanalize the occluded artery in 60 to 90% of patients.[2–4,10,11]

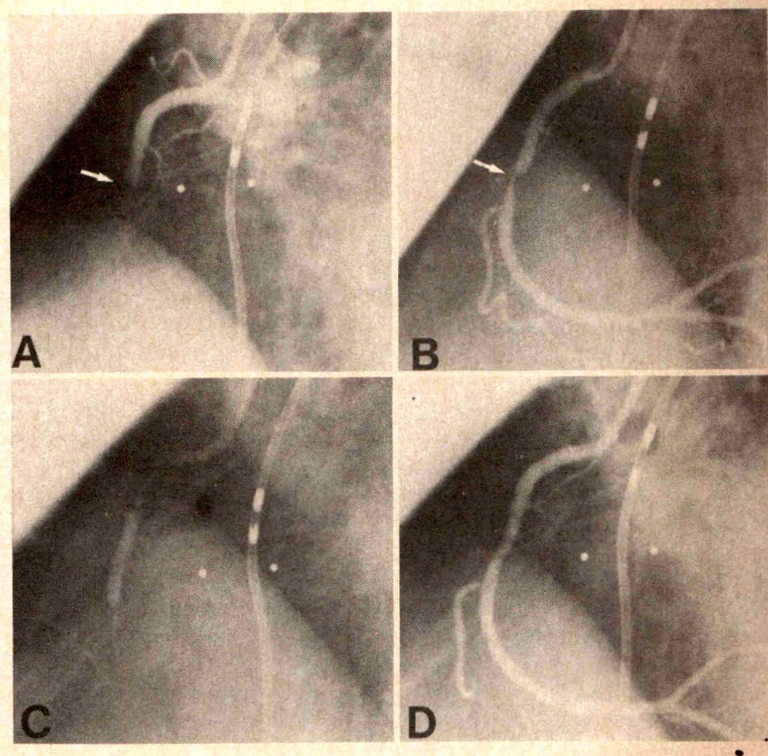

FIGURE 1. Right coronary angiograms (caudocranial left anterior oblique projection) in patient 2, in whom an inferior acute myocardial infarction was evolving. **A,** the right coronary artery is totally occluded in the midsegment (**arrow**). **B,** after recanalization with streptokinase, a severe residual stenosis (**arrow**) is present. **C,** the balloon dilatation catheter has been advanced and is inflated at the site of stenosis. **D,** after angioplasty, the right coronary artery has no residual stenosis.

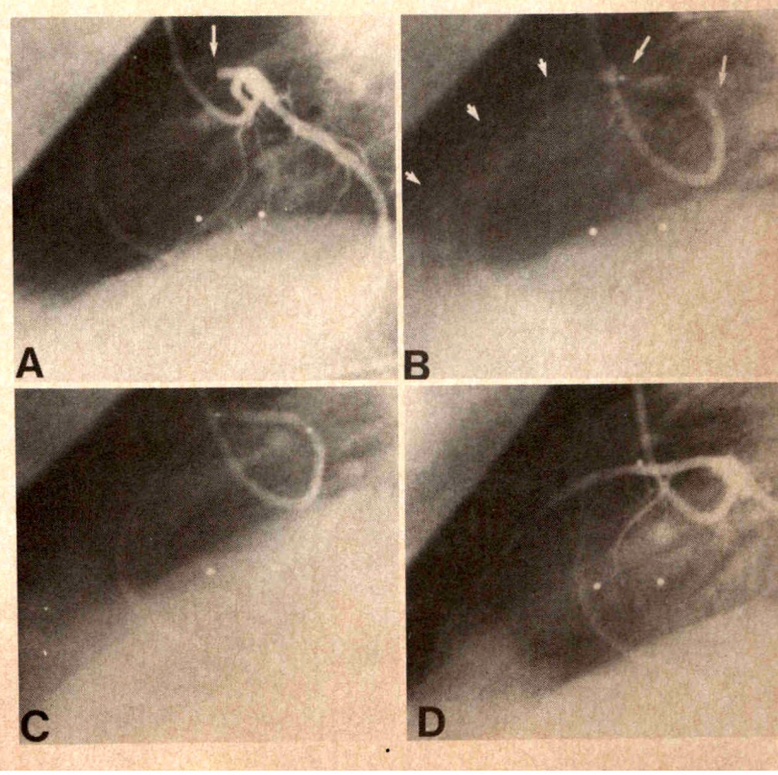

FIGURE 2. Left coronary angiograms (left lateral projection) in patient 11, in whom an anterior acute myocardial infarction was evolving. **A,** the left anterior descending artery is totally occluded in the proximal segment (**arrow**), after unsuccessful administration of streptokinase. **B,** the 2 radiopaque markers (**long arrows**) identify the position of the balloon dilatation catheter, which has been advanced through the occlusion site. The distal portion of the left anterior descending artery is faintly visualized (**short arrows**) with contrast medium injected through the balloon dilatation catheter. **C,** the balloon dilatation catheter is inflated at the site of occlusion. **D,** after angioplasty, no residual stenosis is present.

High-grade stenoses usually remain at the site of the thrombotic occlusion, and may prevent complete revascularization, or result in rethrombosis.[2,4,5] Reocclusion has been reported in 5 to 32% of patients undergoing angiography 7 days to 11 months after thrombolysis.[2–4,12] Furthermore, patients frequently have angina and eventually require surgery or PTCA.[2–4] Thus, PTCA immediately after thrombolysis may be an attractive option to prevent reocclusion and revascularize selected patients with AMI. However, the potential benefits of PTCA should outweigh the risks of the procedure in acutely ill patients, who are frequently hemodynamically unstable, and with a lytic state from STK.[11]

We attempted PTCA immediately after intracoronary STK treatment in a selected group of patients with evolving AMI. PTCA was successful in most patients with residual coronary stenoses, and in some with persistent total coronary occlusions. Follow-up cardiac catheterization, performed in all patients with successful PTCA, revealed persistent patency of the infarct-related artery in most patients, and this was associated with preservation of the initial left ventricular end-diastolic volume. However, 4 of 13 patients (31%) had early reocclusion of the infarct-related artery, which was silent and not associated with a new clinical event in (23%). Complications occurred infrequently, and were associated with a low mortality rate (1 of 18, 5.5%).

In this study, PTCA was successful in 72% of patients, a success rate similar to that of elective PTCA performed in patients with more stable coronary disease, not with evolving AMI.[13,14] We dilated 4 totally occluded arteries. The ability of PTCA to recanalize a totally occluded artery has been reported,[15] and represents a unique therapeutic option in selected patients with AMI in whom thrombolysis is contraindicated or has failed to restore blood flow. New movable guidewire PTCA systems may result in higher success and lower complication rates.[15]

Reocclusion after angioplasty: Four of 13 patients (31%) with successful PTCA of the infarct-related artery had reocclusion of the vessel, demonstrated by angiography before hospital dicharge. One patient (no. 3) had reinfarction with angiographic confirmation of rethrombosis. The other 3 (patients 10, 17 and 18) had clinically silent reocclusions. Although our patient population was small, these findings suggest that a successful PTCA may not prevent rethrombosis, and a clinically uneventful hospital course does not exclude reocclusion. The rethrombosis rate probably could have been reduced by more aggressive anticoagulation. However, it was not our purpose to evaluate the benefits of anticoagulation, but rather the ability of PTCA to prevent thrombotic reocclusion of the infarct-related artery. Thus, despite these limitations, the observation that a successful PTCA does not necessarily prevent rethrombosis is important and should have relevant clinical implications when evaluating therapeutic options in patients with AMI. The relatively high rate of reocclusion observed in our patients could be related to compression and molding of thrombi against the arterial wall, which may propagate and result in reocclusion. Whether additional administration of STK after PTCA, or more aggressive heparin therapy would result in a lower rethrombosis rate is not known.

Left ventricular function after angioplasty: Patients in whom the infarct-related artery remained patent after PTCA had no changes in left ventricular end-diastolic volume. This was associated with a reduction in end-systolic volume and an increase in ejection fraction in those not receiving β-blocking drugs at follow-up angiography. After AMI treated conventionally, there is progressive left ventricular dilatation in proportion to the size of the infarction.[16–19] Thus, the absence of left ventricular dilatation associated with persistent patency of the infarct-related artery probably reflects a reduction of infarct size and preservation of ventricular myocardium.

Hospital mortality: One critically ill patient died during urgent coronary bypass surgery after unsuccessful PTCA. Our population was nonrandomized, selected and too small to allow us to draw conclusions concerning hospital mortality from PTCA during AMI. However, several patients had reduced cardiac index, elevated left ventricular filling pressure, and reduced ejection fraction, variables associated with a high mortality rate in AMI.[20,21] Thus, a mortality rate of 5.5% compares favorably with that observed when more conventional modalities of treatment are used.[22]

Positive Exercise Thallium-201 Test Responses in Patients with Less Than 50% Maximal Coronary Stenosis: Angiographic and Clinical Predictors

KENNETH A. BROWN, MD, MARY OSBAKKEN, MD, CHARLES A. BOUCHER, MD, H. WILLIAM STRAUSS, MD, GERALD M. POHOST, MD, and ROBERT D. OKADA, MD

The incidence and causes of abnormal thallium-201 (Tl-201) myocardial perfusion studies in the absence of significant coronary artery disease were examined. The study group consisted of 100 consecutive patients undergoing exercise Tl-201 testing and coronary angiography who were found to have maximal coronary artery diameter narrowing of less than 50%. Maximal coronary stenosis ranged from 0 to 40%. The independent and relative influences of patient clinical, exercise and angiographic data were assessed by logistic regression analysis. Significant predictors of a positive stress Tl-201 test result were: (1) percent maximal coronary stenosis ($p < 0.0005$), (2) propranolol use ($p < 0.01$), (3) interaction of propranolol use and percent maximal stenosis ($p < 0.005$), and (4) stress-induced chest pain ($p = 0.05$). No other patient variable had a significant influence. Positive Tl-201 test results were more common in patients with 21 to 40% maximal stenosis (59%) than in patients with 0 to 20% maximal stenosis (27%) ($p < 0.01$). Among patients with 21 to 40% stenosis, a positive test response was more common when 85% of maximal predicted heart rate was achieved (75%) than when it was not (40%) ($p < 0.05$). Of 16 nonapical perfusion defects seen in patients with 21 to 40% maximal stenosis, 14 were in the territory that corresponded with such a coronary stenosis. Patients taking propranolol were more likely to have a positive Tl-201 test result (45%) than patients not taking propranolol (22%) ($p < 0.05$). Although patients with stress-induced chest pain more often had a positive Tl-201 test result than those without chest pain, this difference did not reach statistical significance. However, Tl-201 perfusion defects were more frequently seen when typical angina pectoris was elicited than when atypical chest pain developed ($p < 0.05$). The high frequency of Tl-201 defects associated with 21 to 40% stenoses and the close correlation of such defects with myocardial territory supplied by these stenoses suggests that such coronary lesions may have true hemodynamic impact, especially at high levels of stress. In addition, the high incidence of positive Tl-201 studies in patients taking propranolol suggests that an attempt be made to wean patients off β-blocker treatment before Tl-201 exercise testing.

(Am J Cardiol 1985;55:54–57)

Thallium-201 (Tl-201) imaging with injection at exercise is a relatively specific procedure for the detection of myocardial ischemia and scar.[1,2] However, many investigators have observed abnormal Tl-201 responses in patients with noncritical coronary artery disease (CAD). In some cases, the abnormal scans can be attributed to causes other than myocardial ischemia, such as overlying breast tissue or an unusually high gastric fundus. Attenuation due to breast or stomach can frequently be appreciated at the time of image collection and can be corrected by recording additional views. However, even after considering these causes, there remain a group of patients who have definite abnormalities on their Tl-201 scans in the absence of angiographically critical coronary stenoses. To determine the role of the degree of subcritical coronary arterial narrowing and other factors on the incidence of positive Tl-201 scans, 100 consecutive patients with maximal coronary stenosis of less than 50% and who underwent

Tl-201 stress testing were identified and form the basis of this report.

Methods

Patients: The study included 100 consecutive patients (Table I) undergoing both coronary angiography and exercise Tl-201 myocardial imaging for the evaluation of chest pain who were found to have a maximal coronary stenosis of less than 50% diameter narrowing. The range of maximal coronary stenosis was 0 to 40%. Patients were separated into 2 groups: 22 patients with a maximal coronary artery stenosis of 21 to 40% and 78 patients with a maximal stenosis of 0 to 20%, of whom 74 had normal angiograms. Five patients had 21 to 40% maximal stenoses in more than 1 coronary artery (3 two-vessel CAD and 2 three-vessel CAD). Radionuclide imaging and coronary angiography were performed within 2 weeks of each other; the radionuclide study was performed as part of a research protocol and was unrelated to the clinical decision to undergo catheterization. Propranolol was not discontinued for the study. No patient had clinical, radiographic or catheterization evidence of congestive heart failure, valvular disease or congenital heart disease. No patient had historical or electrocardiographic evidence of previous myocardial infarction.

Exercise protocol: Patients exercised either upright on a treadmill according to the standard Bruce protocol (66 patients) or in the supine position using a bicycle ergometer (34 patients). A 12-lead electrocardiogram, heart rate and blood pressure were recorded at rest and at each minute of exercise. For bicycle ergometry the initial workload was 25 W (150 kpm/min), and the workload was increased by 25 W every 3 minutes until fatigue developed. At peak exercise, 1.5 mCi of Tl-201 (New England Nuclear) was injected intravenously and the patient was encouraged to continue exercising for 45 seconds longer. A positive ischemic electrocardiographic response was defined as 1 mm of horizontal or downsloping ST-segment depression. Chest pain elicited during the stress test was recorded and classified as typical or atypical of angina pectoris. Typical angina included pain in the anterior thorax occurring during stress or immediately after exercise that was relieved with rest or nitroglycerin. Atypical angina lacked 1 or more of these features.

Image acquisition: Imaging was performed in the supine position in all patients using an Anger-type gamma camera (Picker Dynacamera, Picker Corp.) equipped with an all-purpose, low-energy, parallel-hole collimator and interfaced to a portable cardiac imaging computer (MUGA-CART, Medical Data Systems). Images were acquired using a 68 to 80-keV window encompassing the mercury x-ray peak of Tl-201. Imaging began with 5 minutes of cessation of exercise in all patients. Six-minute acquisitions were performed in the anterior and 45° left anterior oblique projections. Delayed views in the same projections were obtained 2 to 4 hours later.

Image analysis: Studies were interpreted along with 100 Tl-201 studies in patients with significant (≥50% stenosis) angiographic CAD. All observers were blinded to clinical and angiographic data. Qualitative interpretation of myocardial images was performed from computer-displayed, non-background-subtracted images by 3 experienced observers using previously defined averaged score criteria.[3] Briefly, each image was separated into 3 segments and each segment was scored as either 2 (normal), 1 (reduced activity) or 0 (absent activity). Half-grade scores were allowed for segments with slightly reduced activity (1.5) or nearly absent activity (0.5). Scores for each segment from the 3 observers were averaged and were interpreted as follows: a transient defect was present if a segment's average score on initial image was less than 1.5 and increased by 0.5 or more; a persistent defect was present if the average score on the initial image was less than 1.5 and did not increase by 0.5; a segment was normal if the average score on initial view was 1.5 or more. The presence of either a transient or persistent defect was considered a positive test response for CAD. These criteria have been previously shown to be associated with a high sensitivity and specificity for CAD compared with other qualitative scoring systems.[3]

To assess the correlation of myocardial perfusion defects to territory at risk, the inferior segment was assumed to be supplied by the right coronary artery, the septum and anterior segment by the left anterior descending artery, and the posterior wall by the left circumflex artery. Apical and apicoinferior segments were not assigned coronary territories.

Coronary angiographic data analysis: Coronary angiograms were interpreted by consensus by 2 experienced observers unaware of the patients' history and Tl-201 results. Maximal coronary stenosis was defined by maximal luminal diameter narrowing present in at least 2 projections.

Statistical analysis: Patient data are presented as mean ± standard deviation. A logistic regression analysis (BMDPLR, Health Service Computing Facility, University of California, Los Angeles, CA) was performed to assess the independent relative influence of various patient historical, exercise and angiographic data on positive Tl-201 test results. By this analysis, each variable is initially ranked by its chi-square value. The variable with the highest significant chi-square is entered into the logistic regression model and removed from the list. The process is then repeated stepwise until no significant variable is found. By this analysis, $p < 0.1$ is considered significant.

TABLE I Patient Characteristics

	Upright Exercise (n = 66)	Supine Exercise (n = 34)	p Value
Male:female	36:30	19:15	NS
Propranolol	26	19	NS
≥85% MPHR	37	14	NS
Ischemia on stress ECG	14	4	NS
Stress-induced chest pain	12	4	NS
Maximal stenosis 21–40%	17	10	NS
Maximal stenosis 0–20%	49	24	NS

ECG = electrocardiogram; MPHR = maximal predicted heart rate; NS = not significant.

Results

Patient characteristics: Clinical and exercise data are depicted in Table I. There was no significant difference in any patient parameter for upright compared to supine exercise.

Thallium-201 imaging data: Positive Tl-201 studies were seen in 34 patients. To assess the independent relative influence of method of exercise and the patients' clinical, exercise and angiographic data on the presence of Tl-201 perfusion defects, multiple-step logistic regression analysis was performed. On the initial ranking of patient variables, percent maximal stenosis had the greatest chi-square value and was entered into the logistic regression model. Subsequent analysis steps placed stress-induced chest pain, propranolol use and the interaction of percent maximal stenosis and propranolol use into the model. No other patient variable, including method of exercise (upright vs supine), was found to have significant influence. The significant predictive

TABLE II Significant Predictors of Positive Thallium-201 Test Result

	χ^2	p Value	r
% maximal stenosis	12.69	<0.0005	0.079
Interaction of maximal stenosis and propranolol use	8.32	<0.005	−0.088
Propranolol use	7.42	<0.01	1.39
Stress-induced chest pain	3.77	0.05	1.98
Constant			−1.90

variables and their chi-square, p values and coefficients are shown in Table II.

Positive Tl-201 test results were more common in patients with 21 to 40% maximal stenosis (13 of 22, 59%) than in patients with 20% or less maximal stenosis (21 of 78, 27%; p <0.01) (Fig. 1). Among patients with 21 to 40% stenosis, a positive test result was more common when 85% maximal predicted heart rate was achieved (9 of 12, 75%) than when it was not (4 of 10, 40%; p <0.05). Twenty-two defects were seen among the patients with 21 to 40% maximal stenosis. Of the 16 nonapical defects, 14 (88%) correspond to the territory of a 21 to 40% coronary stenosis.

Patients taking propranolol were more likely to have a positive Tl-201 test response (19 of 42, 45%) than patients not taking propranolol (13 of 58, 22%) (p <0.05) (Fig. 1). Patients with stress-induced chest pain more commonly had a positive Tl-201 test response (8 of 16, 50%) than patients without chest pain (26 of 84, 31%) but this did not reach statistical significance. However, Tl-201 perfusion defects were significantly more common when typical angina pectoris was induced during the stress test (6 of 8, 75%) than when atypical chest pain developed (2 of 8, 25%) (p <0.05).

Discussion

The present study demonstrates that Tl-201 perfusion defects during exercise in patients with maximal coronary stenosis of less than 50% is related to 3 independent factors: maximal coronary artery stenosis, propranolol use, and exercise-induced chest pain.

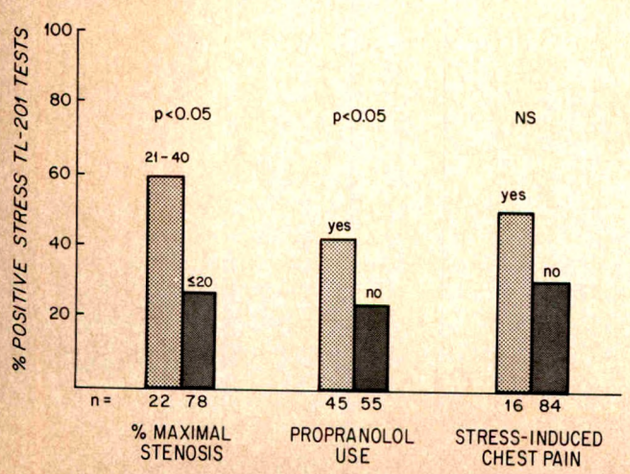

FIGURE 1. Frequency of positive exercise thallium-201 test responses as a function of the 3 significant logistic regression predictors. NS = not significant.

Maximal coronary artery stenosis: Percent maximal coronary artery stenosis was the most important predictor of a positive Tl-201 test response in this patient population. Patients with maximal stenosis of 21 to 40% more often had Tl-201 perfusion defects than patients with maximal stenosis of 20% or less. Although the luminal diameter of a coronary artery must be decreased by approximately 85% to reduce coronary blood flow at rest,[4] stenoses of 50% have been shown to prevent the usual hyperemic response to transient occlusion,[4] and may have hemodynamic significance during stress conditions. Isolated coronary stenoses of less than 50% have conventionally been assumed to be of no clinical importance. However, xenon-133 washout studies have revealed regional reductions in coronary perfusion associated with such lesions.[5] In addition, the usual angiographic grading of a coronary stenosis by its maximal luminal narrowing ignores the possible effect of the length of the lesion[6] and the effect of multiple obstructions of less than 50% within the same vessel.[7] Furthermore, the visual interpretation of coronary angiograms involves considerable inter- and intraobserver variance[8–10] and may lead to difficulty in distinguishing a stenosis of less than 50% from a stenosis greater than 50%. Finally, recent data suggest that visual interpretation of coronary angiographic lesions is a poor predictor of the physiologic importance of coronary stenoses assessed by hyperemic response to temporary occlusion.[11] For these reasons, angiography may underestimate the true hemodynamic impact of lesions that appear to be narrowed by less than 50% in luminal diameter.

Therefore, the segmental defects in Tl-201 uptake during exercise observed in 59% of patients with 21 to 40% coronary stenosis may well reflect a true regional reduction in myocardial blood flow. This is supported by the finding that Tl-201 defects in patients with 21 to 40% stenoses corresponded well to the myocardial territory supplied by such stenoses. In addition, Tl-201 defects in this group of patients were far more common when patients exercised to 85% maximal heart rate (75%) than when lower stress was achieved (40%). Since lesser degrees of obstruction tend to have hemodynamic impact only at higher degrees of coronary blood flow,[4] maximal exercise would be more likely to result in regional hypoperfusion than submaximal exercise. Finally, patients with 21 to 40% maximal coronary stenosis had a significantly higher incidence of Tl-201 defects (59% vs 27%) than patients with 20% maximal stenosis, almost all of whom had entirely normal coronary angiograms. It may therefore be inappropriate to describe exercise Tl-201 defects associated with 21 to 40% coronary lesions as "false positive."

Propranolol use: Two effects of propranolol were observed. First, since the regression coefficient for the interaction of propranolol and percent maximal stenosis was negative, the use of propranolol reduced the likelihood of a positive Tl-201 test for a given maximal coronary artery stenosis. This may reflect the fact that propranolol reduces myocardial work and, hence, cor-

onary blood flow during exercise. As discussed, lesser degrees of stenosis have hemodynamic impact only at higher levels of coronary blood flow. Therefore, with propranolol treatment, borderline coronary stenoses would be less likely to cause regional reductions in coronary blood flow and, thus, less likely to cause a Tl-201 perfusion defect.

Second, propranolol use appeared to have a positive influence on the development of a positive Tl-201 test independent of its interaction with percent maximal stenosis. This influence may be either a direct effect of propranolol on regional myocardial blood flow or Tl-201 uptake or may reflect an indirect effect of patient selection and physician prescription practices. Recent evidence suggests that patients with chest pain and normal coronary arteries angiographically may not have an entirely normal cardiovascular system.[12] Thus, patients with true myocardial ischemia may be more likely to receive propranolol from their physicians, and propranolol use may simply be a marker of underlying cardiac pathology rather than a primary causative agent in producing abnormal Tl-201 tests. Nevertheless, β_2 receptors mediating vasodilation have been described in coronary arteries,[13–15] and propranolol, which has β_1 and β_2 antagonist properties, has been demonstrated to block such adrenergic-induced coronary vasodilation.[13–15] Thus, propranolol may increase coronary vascular tone, and it is possible that Tl-201 defects associated with propranolol are related to hypoperfusion caused by β-antagonist-induced coronary vasospasm. However, regional hypoperfusion associated with segmental defects would be unexpected since differential effects of β blockade on different coronary arteries has not been described.

While propranolol has an independent positive effect and through its interaction with percent maximal stenosis a negative effect on the likelihood of a positive stress Tl-201 test result, the relative values of coefficients (Table II) shows that the net effect of propranolol is to increase the probability of a positive test response.

Exercise-induced chest pain: Chest pain elicited during the stress test was a significant predictor of a positive Tl-201 test result. Such chest pain may well be a clinical manifestation of true myocardial ischemia, because Tl-201 defects were far more common when typical angina pectoris was elicited than when atypical chest pain developed.

Patients: Earlier reports of specificity for stress Tl-201 testing have been approximately 90% for both upright[1] and supine[16] exercise. We do not know why our specificity was considerably lower (73% for 0 to 20% stenosis). It may be due to the high incidence of propranolol use in our series (45%) which the present study has shown to be a positive influence on the development of an abnormal Tl-201 stress test. In addition, all patients in the present series were symptomatic, having presented with chest pain severe enough to warrant coronary angiography, and therefore may not reflect a truly "normal" population. Nevertheless, the patient population in this study is representative of a subgroup of patients likely to undergo exercise Tl-201 testing for evaluation of chest pain.

Clinical implications: The high incidence of Tl-201 defects associated with 21 to 40% stenosis indicates that such lesions may have true hemodynamic impact. This consideration may be important in evaluating the angiographic coronary anatomy of patients who present with exertional chest pain. In addition, this relation should be considered when defining a "normal" coronary artery population for other studies. Although propranolol does not appear to affect overall sensitivity for coronary artery disease,[17] the observation that propranolol was associated with a high incidence of positive Tl-201 test responses in the presence of minor angiographic coronary disease suggests that where clinically acceptable, an attempt should be made to wean patients off β blockade before the exercise Tl-201 study.

Collateral Circulation in Coronary Artery Disease

MacARTHUR A. ELAYDA, MD, VIRENDRA S. MATHUR, MD, ROBERT J. HALL, MD, G. ALI MASSUMI, MD, EFRAIN GARCIA, MD, and CARLOS M. de CASTRO, MD

The coronary arteriograms and left ventriculograms of 202 consecutive patients were reviewed. All had at least 75% diameter reduction of 1 or more major coronary arteries. In 127 patients (63%), at least 1 major branch was totally occluded. Collateral circulation was seen in 125 of these 127 patients (190 of 192 totally occluded arteries). Of the 75 patients without total occlusion, only 2 with 99% (or near-total) occlusion had demonstrable collateral circulation (2 of 208 arteries). In no patient with 75 to 98% diameter narrowing was collateral circulation demonstrated (0 of 164 arteries). An analysis was made of the relation between left ventricular (LV) segmental wall motion and the quality of collateral circulation in 190 totally occluded arteries among 125 patients. Of 126 arteries with good collateral circulation, LV contraction was normal in 21%, hypokinetic in 48% and akinetic/dyskinetic in 29%. Of 64 arteries with poor collateral circulation, LV contraction was normal in 23%, hypokinetic in 55% and akinetic/dyskinetic in 20%. There was no statistically significant difference between the effect of good or poor collateral circulation on LV function. These data indicate that collateral circulation cannot be seen angiographically unless there is total or near-total occlusion, and that the presence of collateral circulation does not correlate with LV wall motion abnormalties, i.e., akinetic area, despite good collateral flow or normal wall motion despite absent or poor collateral flow.

(Am J Cardiol 1985;55:58-60)

It is generally accepted that collateral blood vessels are real and potential channels in the normal heart.[1] Collateral vessels represent alternative routes of flow that develop and enlarge as a result of a pressure difference across segments of coronary arteries caused by an obstruction.[2-8] As a result, collateral circulation is not due to formation of new vessels, but rather the utilization of vessels that preexist but are nonfunctional until the need arises.[9-12] Considerable controversy continues over the function and effectiveness of coronary vessels that act as a compensatory mechanism to protect the myocardium against ischemia. The present study was designed to study the circumstances that promote collateral circulation and their protective role. The study was prompted by the frequently asked question posed by many clinicians, "Does this patient have collaterals?" and a frequent misstatement, "This patient has good collaterals and *natural bypasses.*"

Methods

A total of 211 consecutive coronary angiograms and left ventriculograms of patients with significant coronary artery disease (CAD) were studied. Significant CAD was defined as at least 75% diameter reduction of 1 or more major coronary arteries. Of these 211 angiograms, 202 were selected for the study based on good quality. Selective coronary angiography was performed in multiple projections at 60 frames/s. Evaluation of the angiograms was done by at least 2 investigators, independently, and then jointly to ensure accuracy.

Stenosis of the coronary arteries was estimated as a percentage of luminal narrowing based on diameter reduction. Estimation of coronary stenosis up to 75% was done using a caliper; however, higher grades of obstruction (between 75 and 99%) were somewhat arbitrary and derived from close inspection of the involved segment through multiple views.

Collateral circulation was considered present if there was opacity of the right or its branches after injection of contrast medium into the left coronary artery, or vice versa. Collateral vessels were also considered present if the distal segment of a totally occluded vessel was opacified late after injection in the proximal segment. The actual collateral channels joining the distal and proximal segments of obstructed vessels were not necessarily visualized in each patient. The degree of opacity of the distal segment was considered an indication of the adequacy of the collateral circulation. Collaterals were considered good if the opacity of the distal segment was 50%

TABLE I Occurrence of Collateral Circulation in the Presence of 75% to 100% Stenotic Lesions

or more of the proximal segment, and poor if the opacity of the distal segment was less than 50% of the proximal segment.

Regional ventricular wall motion: Performance of the various left ventricular (LV) regions or segments was evaluated by biplane left ventriculography. Each region was graded as normal, hypokinetic, akinetic or dyskinetic. The relation of collateral vessels and regional wall motion was studied in all patients with complete occlusion and correlated with the adequacy of collateral circulation.

Results

In the total population, there were 127 (63%) patients in whom at least 1 major branch was totally occluded. Collateral circulation was seen in 125 of these 127 patients (190 of 192 totally occluded arteries in 127 patients). In the 75 patients without total occlusion, only 2 (3%) with 99% (or near-total) occlusion had demonstrable collateral circulation (2 of 208 arteries with 75 to 99% stenosis). The distribution of narrowings in each major artery or its branches, according to severity, and the presence of collateral vessels is listed in Table I. In the arteries critically stenosed, 75 to 99%, but not totally occluded, collateral circulation could be angiographically visualized in only 2 patients, both of whom had near-total occlusion (99% stenosis). All patients with total occlusion had demonstrable collateral circulation, with the exception of 2 in whom the occluded segments were in a totally akinetic/dyskinetic LV area. In no instance of 75 to 98% stenosis was collateral circulation demonstrated angiographically.

The quality of collateral circulation in relation to totally occluded vessels, respectively, is shown in Table II. The relation of LV segmental wall motion with the quality of collateral circulation is shown in Figure 1. No statistically significant difference was noted between the effects of poor and good collateral circulation on LV wall motion (chi-square analysis).

Discussion

Our results differ from previous observations by other investigators who claim observance of collateral circulation in vessels with stenoses of 50 to 95%.[6,7,13–19] These claims have led clinicians to ask the question, "Does my patient have collaterals?", implying that some patients with 50 to 95% stenosis have collaterals and others do not and patients with collaterals have a better prognosis. Although lesions with 50 to 90% occlusion *can* produce myocardial ischemia and anginal pain, according to our data they are never accompanied by collateral circulation that is visible angiographically. Our data indicate that angiographically demonstrable collaterals depend on the presence of a totally occluded artery rather than any variability from patient to patient; as collateral vessels are almost always present if an artery is totally occluded. It appears from our data that the resting pressure in the distal segment of a stenosed artery must be very different in patients with or without 100% obstruction. In the presence of 100% obstruction, the distal pressure is low enough to permit angiographic collateral flow; with less than 100% obstruction, the distal pressure may be quite low but still not as low as in 100% occluded arteries and therefore angiographic collateral flow does not occur. An older report that claimed presence of

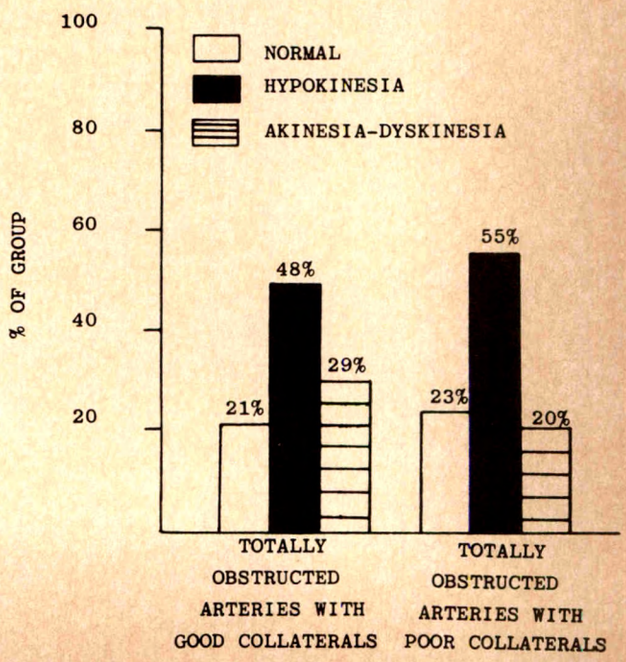

FIGURE 1. Left ventricular segmental wall motion in relation to the quality of collateral circulation. The proportion of normal, hypokinetic and akinetic segments is similar in the group with good and the group with poor collateral vessels.

collaterals in patients with 50 to 75% stenosis[16,19] might have observed a 50% lesion of a major vessel and missed the 100% occlusion of a branch and what was actually seen as collaterals was only for that branch.

Possible reasons for failure to demonstrate collaterals in totally occluded arteries include: (1) poor angiographic technique; (2) failure to use nitroglycerin, which has been shown to elicit primary vasodilation of coronary collateral channels[8,20]; and (3) failure to properly visualize the area of the missing vessel in the late phase. These latter techniques are now used routinely and have greatly helped in the study of difficult cases.

Controversy continues over the role of collateral circulation in preserving LV function in patients with CAD. Some investigators have reported that function may be substantially better when collateral vessels have developed[9,17,24–26]; our data and data from other studies[13–15,21–23] do not support this. Our results show that normal wall motion distal to an occluded segment is possible, even with poor collateral circulation. We have no good explanation for this, but the conclusion that infarction is avoidable even with total occlusion of an artery and poor collaterals is inescapable. Conversely, LV segmental motion can be akinetic despite good collateral circulation. We can neither retrospectively determine if the collateral circulation was good at the time of infarction nor determine the temporal sequence of total occlusion, good collateral development and clinical infarction. We must draw 1 of 2 conclusions: (1) infarction took place despite good collateral vessels, or (2) good collaterals developed after infarction in an akinetic or dyskinetic area.

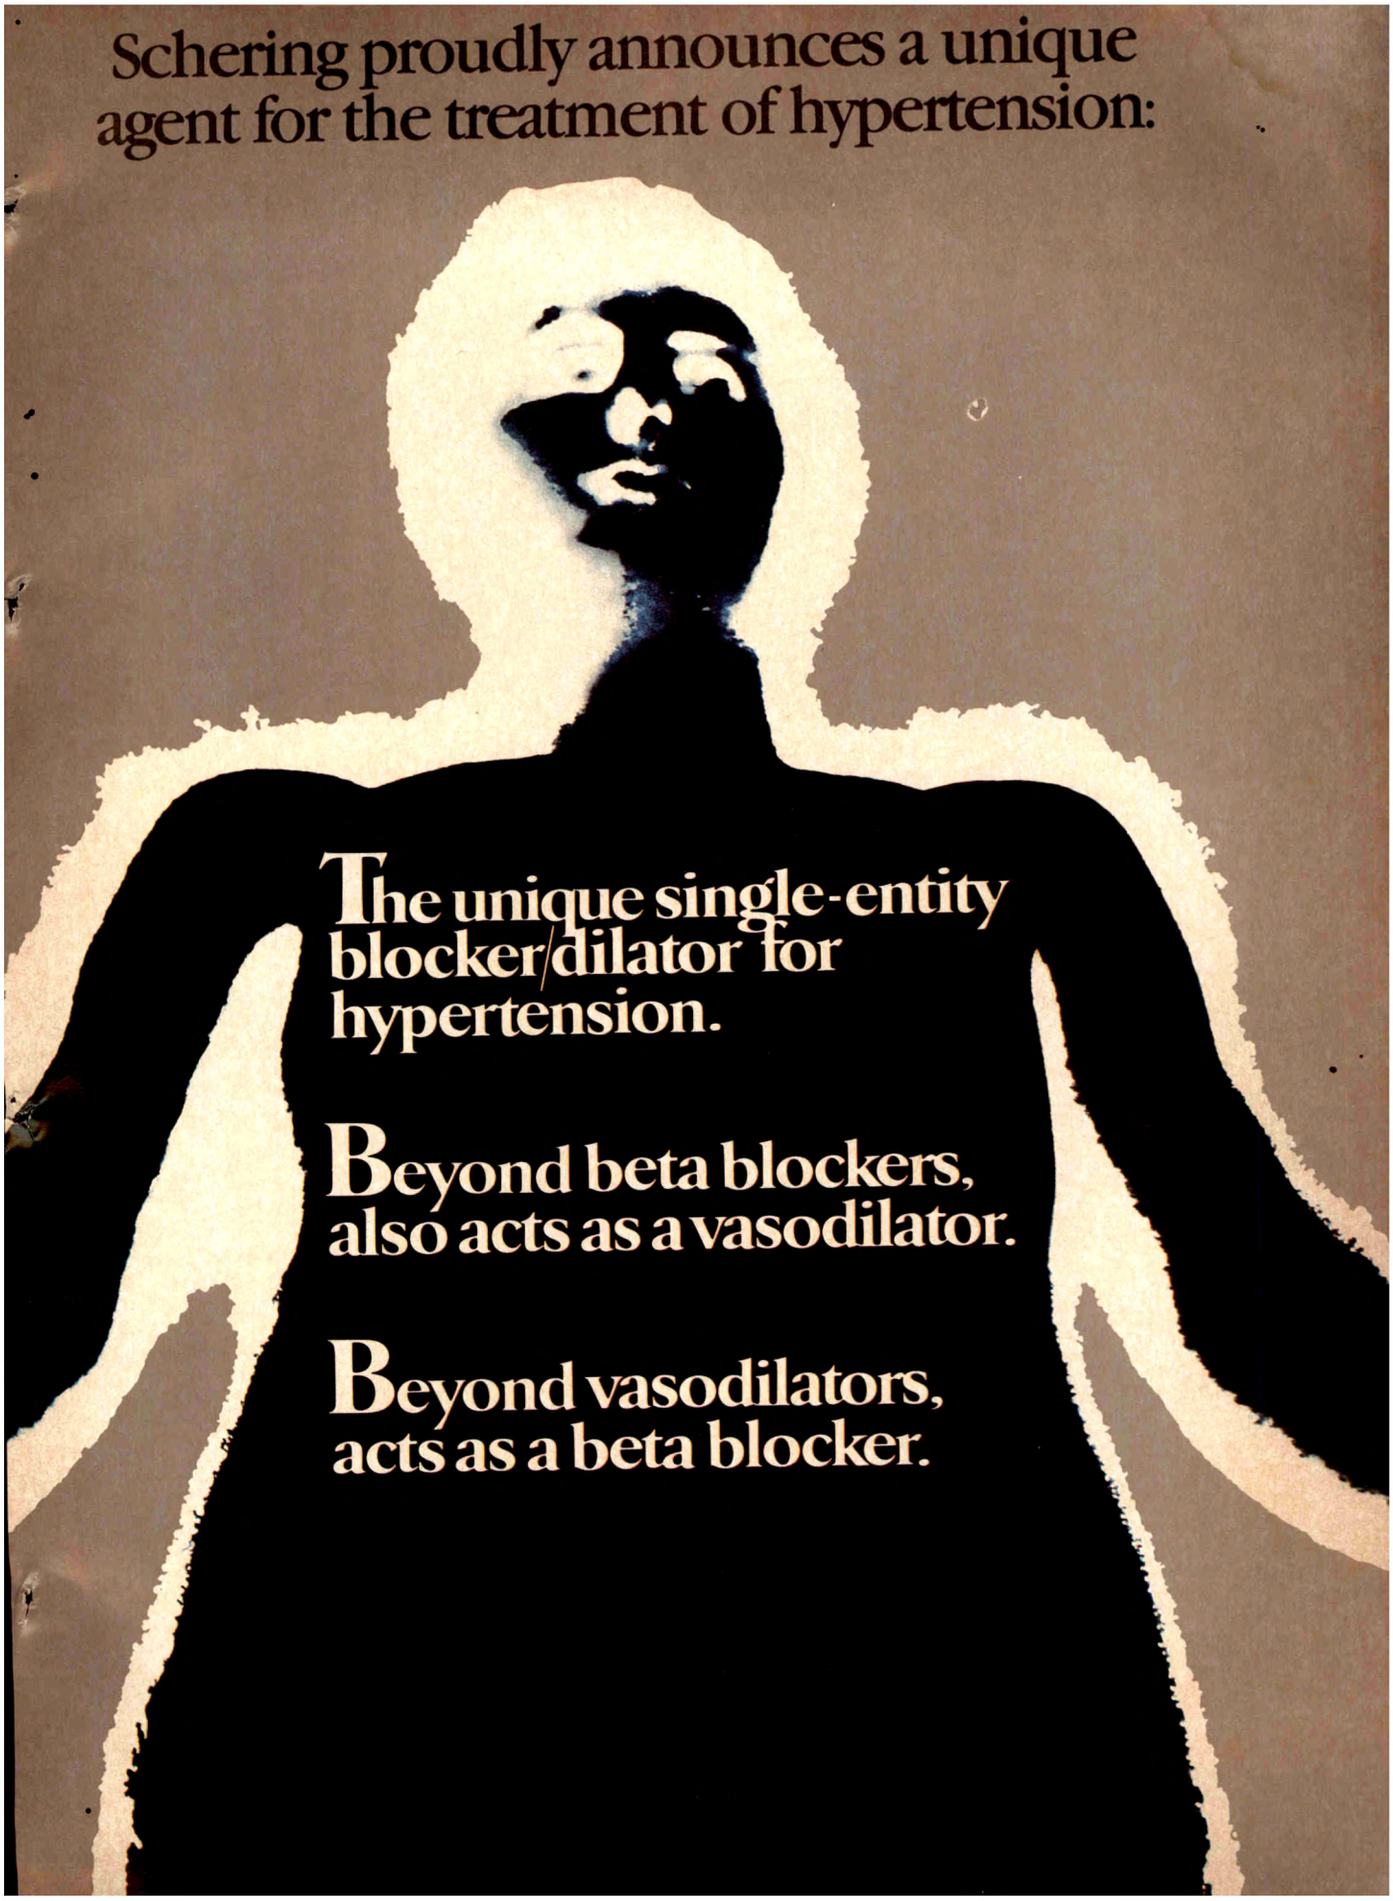
Schering proudly announces a unique agent for the treatment of hypertension:



The unique single-entity blocker/dilator for hypertension.

Beyond beta blockers, also acts as a vasodilator.

Beyond vasodilators, acts as a beta blocker.

New for hypertension

NORMODYNE®

Tablets (labetalol HCl)

Schering

The unique single-entity blocker/dilator

Normodyne® (labetalol HCl) is a unique single-entity agent. It is not a combination but, rather, a single substance that acts as a beta blocker as well as a vasodilator. It offers the advantages of both while avoiding many of their disadvantages. Beyond beta blockers, it also acts as a vasodilator to lower blood pressure. Beyond vasodilators, it acts as a beta blocker to blunt excessive cardiac response to exercise in hypertensives.

- ☐ A demonstrated safety profile.
- ☐ Favorable side-effects profile.
- ☐ Unsurpassed efficacy in mild to moderate hypertension.
- ☐ Useful in a wide diversity of patient types.
- ☐ Well documented in hundreds of clinical studies.
- ☐ Millions of patients treated worldwide.
- ☐ Convenient b.i.d. dosage.

Unlike any single-entity antihypertensive you've ever used.

NORMODYNE®
Tablets (labetalol HCl)

...brief summary of prescribing information

13071918

PRODUCT INFORMATION

NORMODYNE®
brand of labetalol hydrochloride
Tablets
BRIEF SUMMARY

INDICATIONS AND USAGE
NORMODYNE (labetalol HCl) Tablets are indicated in the management of hypertension. NORMODYNE Tablets may be used alone or in combination with other antihypertensive agents, especially thiazide and loop diuretics.

CONTRAINDICATIONS
NORMODYNE (labetalol HCl) Tablets are contraindicated in bronchial asthma, overt cardiac failure, greater than first degree heart block, cardiogenic shock, and severe bradycardia. (See WARNINGS.)

WARNINGS
Cardiac Failure Sympathetic stimulation is a vital component supporting circulatory function in congestive heart failure. Beta blockade carries a potential hazard of further depressing myocardial contractility and precipitating more severe failure. Although beta-blockers should be avoided in overt congestive heart failure, if necessary, labetalol HCl can be used with caution in patients with a history of heart failure who are well-compensated. Congestive heart failure has been observed in patients receiving labetalol HCl. Labetalol HCl does not abolish the inotropic action of digitalis on heart muscle.

In Patients Without a History of Cardiac Failure In patients with latent cardiac insufficiency, continued depression of the myocardium with beta-blocking agents over a period of time can in some cases lead to cardiac failure. At the first sign or symptom of impending cardiac failure, patients should be fully digitalized and/or be given a diuretic, and the response observed closely. If cardiac failure continues, despite adequate digitalization and diuretic, NORMODYNE (labetalol HCl) therapy should be withdrawn (gradually if possible).

Exacerbation of Ischemic Heart Disease Following Abrupt Withdrawal Angina pectoris has not been reported upon labetalol HCl discontinuation. However, hypersensitivity to catecholamines has been observed in patients withdrawn from beta-blocker therapy; exacerbation of angina and, in some cases, myocardial infarction have occurred after *abrupt* discontinuation of such therapy. When discontinuing chronically administered NORMODYNE (labetalol HCl), particularly in patients with ischemic heart disease, the dosage should be gradually reduced over a period of one to two weeks and the patient should be carefully monitored. If angina markedly worsens or acute coronary insufficiency develops, NORMODYNE (labetalol HCl) administration should be reinstituted promptly, at least temporarily, and other measures appropriate for the management of unstable angina should be taken. Patients should be warned against interruption or discontinuation of therapy without the physician's advice. Because coronary artery disease is common and may be unrecognized, it may be prudent not to discontinue NORMODYNE (labetalol HCl) therapy abruptly even in patients treated only for hypertension.

Nonallergic Bronchospasm (e.g., chronic bronchitis and emphysema) Patients with bronchospastic disease should, in general, not receive beta-blockers. NORMODYNE may be used with caution, however, in patients who do not respond to, or cannot tolerate, other antihypertensive agents. It is prudent, if NORMODYNE is used, to use the smallest effective dose, so that inhibition of endogenous or exogenous beta-agonists is minimized.

Pheochromocytoma Labetalol HCl has been shown to be effective in lowering the blood pressure and relieving symptoms in patients with pheochromocytoma. However, paradoxical hypertensive responses have been reported in a few patients with this tumor; therefore, use caution when administering labetalol HCl to patients with pheochromocytoma.

Diabetes Mellitus and Hypoglycemia Beta-adrenergic blockade may prevent the appearance of premonitory signs and symptoms (e.g., tachycardia) of acute hypoglycemia. This is especially important with labile diabetics. Beta-blockade also reduces the release of insulin in response to hypoglycemia; it may therefore be necessary to adjust the dose of antidiabetic drugs.

Major Surgery The necessity or desirability of withdrawing beta-blocking therapy prior to major surgery is controversial. Protracted severe hypotension and difficulty in restarting or maintaining a heart beat have been reported with beta-blockers. The effect of labetalol HCl's alpha-adrenergic activity has not been evaluated in this setting.

A synergism between labetalol HCl and halothane anesthesia has been shown (see **Drug Interactions**).

PRECAUTIONS
General *Impaired Hepatic Function* NORMODYNE (labetalol HCl) Tablets should be used with caution in patients with impaired hepatic function since metabolism of the drug may be diminished.

Jaundice or Hepatic Dysfunction On rare occasions, labetalol HCl has been associated with jaundice (both hepatic and cholestatic). It is therefore recommended that treatment with labetalol HCl be stopped immediately, should a patient develop jaundice or laboratory evidence of liver injury. Both have been shown to be reversible on stopping therapy.

Information for Patients

As with all drugs with beta-blocking activity, certain advice to patients being treated with labetalol HCl is warranted. This information is intended to aid in the safe and effective use of this medication. It is not a disclosure of all possible adverse or intended effects. While no incident of the abrupt withdrawal phenomenon (exacerbation of angina pectoris) has been reported with labetalol HCl, dosing with NORMODYNE Tablets should not be interrupted or discontinued without a physician's advice. Patients being treated with NORMODYNE Tablets should consult a physician at any sign of impending cardiac failure. Also, transient scalp tingling may occur, usually when treatment with NORMODYNE Tablets is initiated (see **ADVERSE REACTIONS**).

Laboratory Tests

As with any new drug given over prolonged periods, laboratory parameters should be observed over regular intervals. In patients with concomitant illnesses, such as impaired renal function, appropriate tests should be done to monitor these conditions.

Drug Interactions

In one survey, 2.3% of patients taking labetalol HCl in combination with tricyclic antidepressants experienced tremor as compared to 0.7% reported to occur with labetalol HCl alone. The contribution of each of the treatments to this adverse reaction is unknown but the possibility of a drug interaction cannot be excluded.

Drugs possessing beta-blocking properties can blunt the bronchodilator effect of beta-receptor agonist drugs in patients with bronchospasm; therefore, doses greater than the normal anti-asthmatic dose of beta-agonist bronchodilator drugs may be required.

Cimetidine has been shown to increase the bioavailability of labetalol HCl. Since this could be explained either by enhanced absorption or by an alteration of hepatic metabolism of labetalol HCl, special care should be used in establishing the dose required for blood pressure control in such patients.

Synergism has been shown between halothane anesthesia and intravenously administered labetalol HCl. During controlled hypotensive anesthesia using labetalol HCl in association with halothane, high concentrations (3% or above) of halothane should not be used because the degree of hypotension will be increased and because of the possibility of a large reduction in cardiac output and an increase in central venous pressure. The anesthesiologist should be informed when a patient is receiving labetalol HCl.

Labetalol HCl blunts the reflex tachycardia produced by nitroglycerin without preventing its hypotensive effect. If labetalol HCl is used with nitroglycerin in patients with angina pectoris, additional antihypertensive effects may occur.

Drug/Laboratory Test Interactions

The presence of a metabolite of labetalol in the urine may result in falsely increased levels of urinary catecholamines when measured by a nonspecific trihydroxyindole (THI) reaction. In screening patients suspected of having a pheochromocytoma and being treated with labetalol HCl, specific radioenzymatic or high performance liquid chromatography assay techniques should be used to determine levels of catecholamines or their metabolites.

Carcinogenesis, Mutagenesis, Impairment of Fertility

Long-term oral dosing studies with labetalol HCl for 18 months in mice and for 2 years in rats showed no evidence of carcinogenesis. Studies with labetalol HCl, using dominant lethal assays in rats and mice, and exposing microorganisms according to modified Ames tests, showed no evidence of mutagenesis.

Pregnancy Category C

Teratogenic studies have been performed with labetalol in rats and rabbits at oral doses up to approximately 6 and 4 times the MRHD, respectively. No reproducible evidence of fetal malformations was observed. Increased fetal resorptions were seen in both species at doses approximating the MRHD. There are no adequate and well-controlled studies in pregnant women. Labetalol should be used during pregnancy only if the potential benefit justifies the potential risk to the fetus.

Nonteratogenic Effects

Infants of mothers who were treated with labetalol HCl for hypertension during pregnancy did not appear to be adversely affected by the drug. Oral administration of labetalol to rats during late gestation through weaning at doses of 2 to 4 times the MRHD caused a decrease in neonatal survival.

Labor and Delivery

Labetalol HCl given to pregnant women with hypertension did not appear to affect the usual course of labor and delivery.

Nursing Mothers

Small amounts of labetalol (approximately 0.004% of the maternal dose) are excreted in human milk. Caution should be exercised when NORMODYNE Tablets are administered to a nursing woman.

Pediatric Use

Safety and effectiveness in children have not been established.

ADVERSE REACTIONS
Most adverse effects are mild, transient and occur early in the course of treatment. In controlled clinical trials of 3 to 4 months duration, discontinuation of NORMODYNE (labetalol HCl) Tablets due to one or more adverse effect was required in 7% of all patients. In these same trials, beta-blocker control agents led to discontinuation in 8 to 10% of patients, and a centrally acting alpha-agonist in 30% of patients.

The incidence rates of adverse reactions listed in the following table were derived from multicenter controlled clinical trials, comparing labetalol HCl, placebo, metoprolol and propranolol, over treatment periods of 3 and 4 months. Where the frequency of adverse effects for labetalol HCl and placebo is similar, causal relationship is uncertain. The rates are based on adverse reactions considered probably drug-related by the investigator. If all reports are considered, the rates are somewhat higher (e.g., dizziness 20%, nausea 14%, fatigue 11%), but the overall conclusions are unchanged.

	Labetalol HCl (N = 227) %	Placebo (N = 98) %	Propranolol (N = 84) %	Metoprolol (N = 49) %
Body as a whole				
fatigue	5	0	12	12
asthenia	1	1	1	0
headache	2	1	1	2
Gastrointestinal

The adverse effects were reported spontaneously and are representative of the incidence of adverse effects that may be observed in a properly selected hypertensive patient population, i.e., a group excluding patients with bronchospastic disease, overt congestive heart failure, or other contraindications to beta-blocker therapy.

Clinical trials also included studies utilizing daily doses up to 2400 mg in more severely hypertensive patients. Certain of the side effects increased with increasing dose as shown in the table below which depicts the entire U.S. therapeutic trials data base for adverse reactions that are clearly or possibly dose related.

Labetalol HCl

Daily Dose (mg)	200	300	400	600	800	900	1200	1600	2400
Number of Patients	522	181	606	608	503	117	411	242	175
Dizziness (%)	2	3	3	3	5	1	9	13	16
Fatigue	2	1	4	4	5	3	7	6	10

Labetalol HCl (continued)

Daily Dose (mg)	200	300	400	600	800	900	1200	1600
Number of Patients	522	181	606	608	503	117	411	242
Nausea	<1	0	1	2	4	0	7	11
Vomiting	0	0	<1	<1	<1	0	1	2
Dyspepsia	1	0	2	1	1	0	2	2
Paresthesias	2	0	2	2	1	1	2	5
Nasal Stuffiness	1	1	2	2	2	2	4	5
Ejaculation Failure	0	2	1	2	3	0	4	3
Impotence	1	1	1	1	2	4	3	4
Edema	1	0	1	1	1	0	1	2

In addition, a number of other less common adverse events have been reported in clinical trials or the literature:

Central and Peripheral Nervous Systems Paresthesias, most frequently described as scalp tingling. In most cases, it was mild, transient and usually occurred at the beginning of treatment.

Collagen Disorders Systemic lupus erythematosus; positive anti-nuclear factor (ANF).

Eyes Dry eyes.

Immunological System Antimitochondrial antibodies.

Liver and Biliary System Cholestasis with or without jaundice.

Musculo-Skeletal System Muscle cramps; toxic myopathy.

Respiratory System Bronchospasm.

Skin and Appendages Rashes of various types, such as generalized maculo-papular; lichenoid; urticarial; bullous lichen planus; psoriaform facial erythema; Peyronie's disease; reversible alopecia.

Urinary System Difficulty in micturition, including acute urinary bladder retention.

Following approval for marketing in the United Kingdom, a monitored release survey involving approximately 6,800 patients was conducted for further safety and efficacy evaluation of this product. Results of this survey indicate that the type, severity, and incidence of adverse effects were comparable to those cited above.

Potential Adverse Effects

In addition, other adverse effects not listed above have been reported with other beta-adrenergic blocking agents.

Central Nervous System Reversible mental depression progressing to catatonia; an acute reversible syndrome characterized by disorientation for time and place, short-term memory loss, emotional lability, slightly clouded sensorium, and decreased performance on neuropsychometrics.

Cardiovascular Intensification of AV block. See **CONTRAINDICATIONS.**

Allergic Fever combined with aching and sore throat; laryngospasm; respiratory distress.

Hematologic Agranulocytosis; thrombocytopenic or nonthrombocytopenic purpura.

Gastrointestinal Mesenteric artery thrombosis; ischemic colitis.

The oculomucocutaneous syndrome associated with the beta-blocker practolol has not been reported with labetalol HCl.

Clinical laboratory tests: There have been reversible increases of serum transaminases in 4% of patients treated with labetalol HCl and tested, and more rarely, reversible increases in blood urea.

OVERDOSAGE
Overdosage with NORMODYNE (labetalol HCl) Tablets causes excessive hypotension which is posture sensitive, and sometimes, excessive bradycardia. Patients should be laid supine and their legs raised if necessary to improve the blood supply to the brain. The following additional measures should be employed if necessary: *Excessive bradycardia* — administer atropine (3.0 mg). If there is no response to vagal blockade, administer isoproterenol cautiously. *Cardiac failure* — administer a digitalis glycoside and a diuretic. *Hypotension* — administer vasopressors, e.g., norepinephrine. There is pharmacological evidence that norepinephrine may be the drug of choice. *Bronchospasm* — administer a beta$_2$-stimulating agent and/or a theophylline preparation.

Gastric lavage or pharmacologically induced emesis (using syrup of ipecac) is useful for removal of the drug shortly after ingestion. Labetalol HCl can be removed from the general circulation by hemodialysis.

The oral LD_{50} value of labetalol HCl in the mouse is approximately 600 mg/kg and in the rat is greater than 2 gm/kg. The intravenous LD_{50} in these species is 50 to 60 mg/kg.

DOSAGE AND ADMINISTRATION
DOSAGE MUST BE INDIVIDUALIZED. The recommended initial dose is 100 mg twice daily whether used alone or added to a diuretic regimen. After 2 or 3 days, using standing blood pressure as an indicator, dosage may be titrated in increments of 100 mg bid every 2 or 3 days. The usual maintenance dosage of labetalol HCl is between 200 and 400 mg twice daily.

Since the full antihypertensive effect of labetalol HCl is usually seen within the first one to three hours of the initial dose or dose increment, the assurance of a lack of an exaggerated hypotensive response can be clinically established in the office setting. The antihypertensive effects of continued dosing can be measured at subsequent visits, approximately 12 hours after a dose, to determine whether further titration is necessary.

Patients with severe hypertension may require from 1200 mg to 2400 mg per day, with or without thiazide diuretics. Should side effects (principally nausea or dizziness) occur with these doses administered bid, the same total daily dose administered tid may improve tolerability and facilitate further titration. Titration increments should not exceed 200 mg bid.

When a diuretic is added, an additive antihypertensive effect can be expected. In some cases this may necessitate a labetalol HCl dosage adjustment. As with most antihypertensive drugs, optimal dosages of NORMODYNE Tablets are usually lower in patients also receiving a diuretic.

When transferring patients from other antihypertensive drugs, NORMODYNE Tablets should be introduced as recommended and the dosage of the existing therapy progressively decreased.

HOW SUPPLIED
NORMODYNE (labetalol HCl) Tablets, 200 mg, white, round, scored, film-coated tablets engraved on one side with Schering and product identification numbers 752, and on the other side the number 200 for the strength; bottles of 100 (NDC-0085-0752-04), 500 (NDC-0085-0752-05), box of 100 for unit-dose dispensing (NDC-0085-0752-08), and Patient Calendar Package of 56 (4 bottles of 14 tablets) (NDC-0085-0752-03).

NORMODYNE (labetalol HCl) Tablets, 300 mg, blue, round, film-coated tablets engraved on one side with Schering and product identification numbers 438, and on the other side the number 300 for the strength; bottles of 100 (NDC-0085-0438-03), 500 (NDC-0085-0438-05), box of 100 for unit-dose dispensing (NDC-0085-0438-06), and Patient Calendar Package of 56 (4 bottles of 14 tablets) (NDC-0085-0438-02).

NORMODYNE (labetalol HCl) Tablets should be stored between 2° and 30°C (36° and 86°F).

NORMODYNE (labetalol HCl) Tablets in the unit-dose boxes should be protected from excessive moisture.

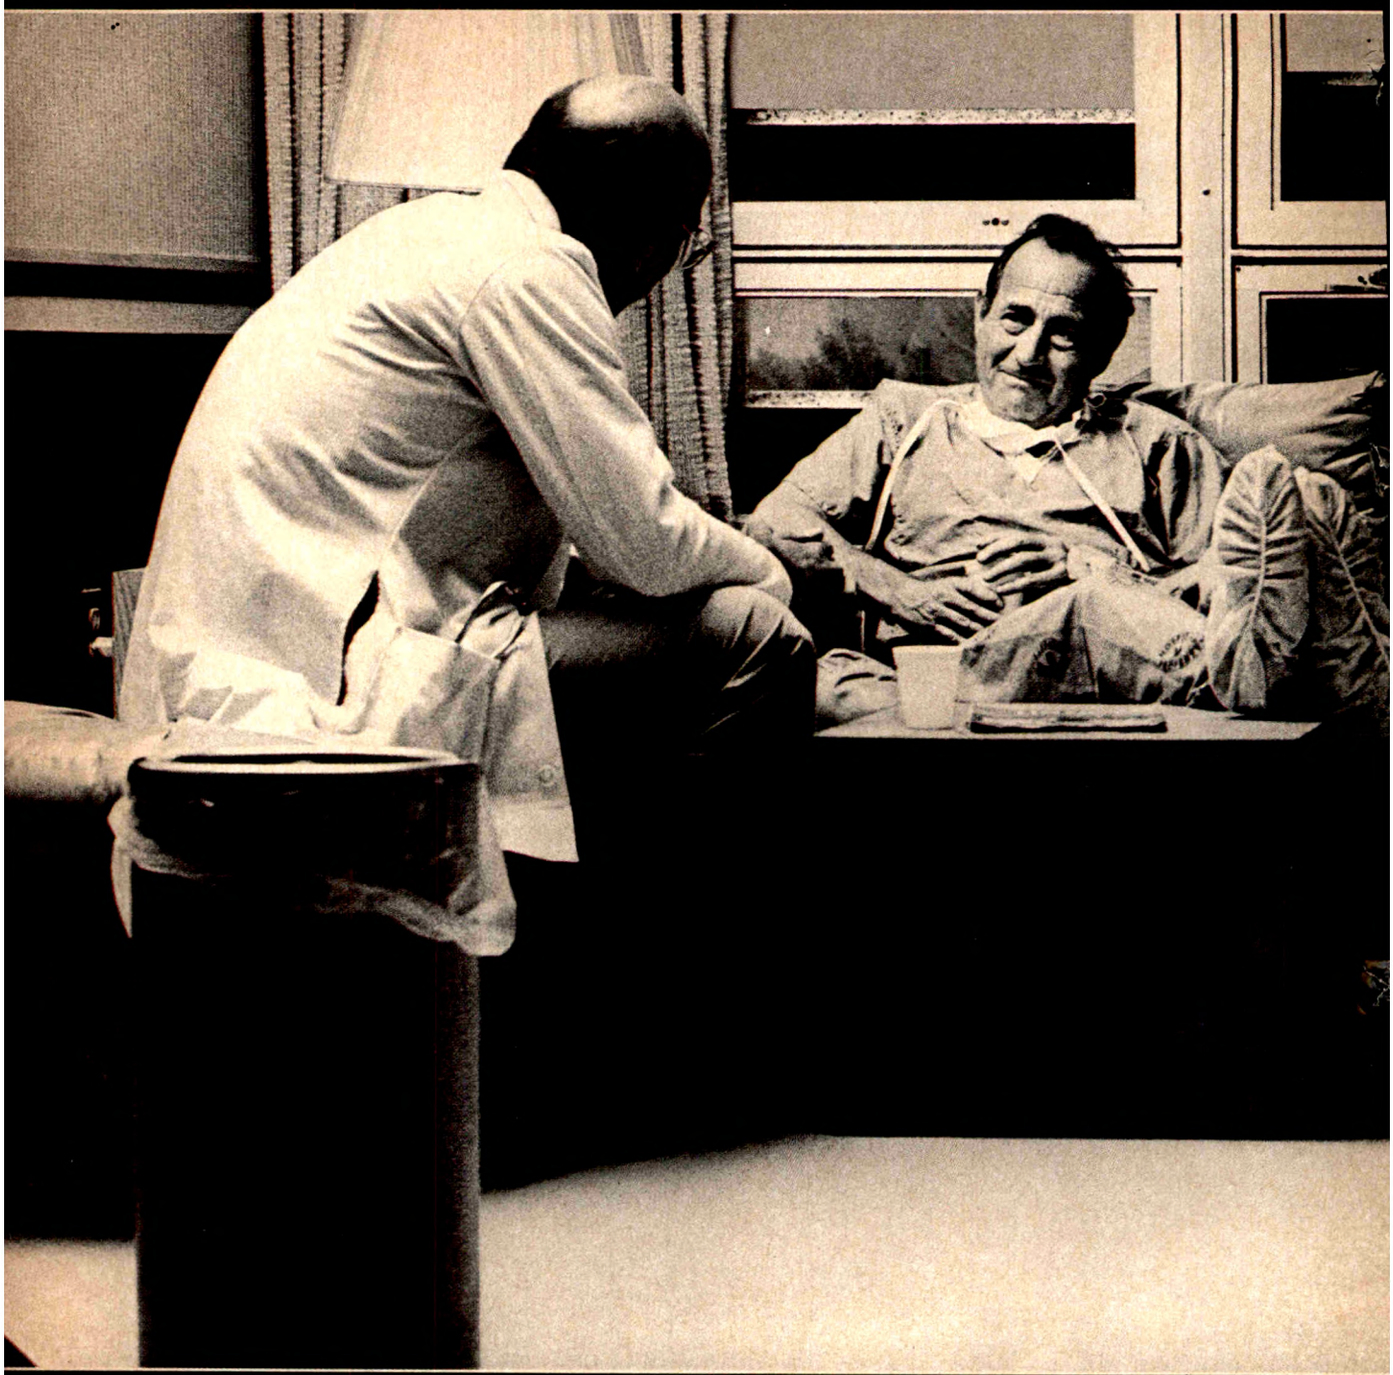
TOUGHER THAN A VVI, RIGHT? WRONG.



Technology often feeds on itself, complicating its own support system.

Not so with a Cordis Sequicor® or Gemini® pacer.

Our hand-held Cordis Programmer III continues to set the standard for simplicity, portability and efficiency. With it you can program *any* Cordis pacer in seconds.

The process is no more complicated than using a good pocket calculator.

Along with the Programmer III, comes the Cordis representative, thoroughly supportive and thoroughly trained in every aspect of DDD pacing and always there when needed.

Another mainstay of our support system is the Cordis accredited CME and nursing educational programs.

These and other Cordis training programs cover the gamut of DDD pacing from classroom instruction to text and audio-visual programs to implant workshops where you actually place atrial leads.

What we do is keep our pacer systems simple and our support system strong.

So you can concentrate on what really counts.

On nitrates,
but angina still
strikes...

After a nitrate, add ISOPTIN®
(verapamil HCl/Knoll)

To protect your patients, as well as their quality of life, add Isoptin instead of a beta blocker.

First, Isoptin not only reduces myocardial oxygen demand by reducing peripheral resistance, but also increases coronary perfusion by preventing coronary vasospasm and dilating coronary arteries — both normal and stenotic. These are antianginal actions that no beta blocker can provide.

Second, Isoptin spares patients the beta-blocker side effects that may compromise the quality of life.

With Isoptin, fatigue, bradycardia and mental depression are rare. Unlike beta blockers, Isoptin can safely be given to patients with asthma, COPD, diabetes or peripheral vascular disease. Serious adverse reactions with Isoptin are rare at recommended doses; the single most common side effect is constipation (6.3%).

Cardiovascular contraindications to the use of Isoptin are similar to those of beta blockers: severe left ventricular dysfunction, hypotension (systolic pressure <90 mm Hg) or cardiogenic shock, sick sinus syndrome (if no artificial pacemaker is present) and second- or third-degree AV block.

So, the next time a nitrate is not enough, add Isoptin... for more comprehensive antianginal protection without side effects which may cramp an active life style.

ISOPTIN. Added antianginal protection without beta-blocker side effects.

Please see brief summary on following page.

ISOPTIN® TABLETS
(verapamil HCl/Knoll)
80 mg and 120 mg

Contraindications: Severe left ventricular dysfunction (see *Warnings*), hypotension (systolic pressure <90 mm Hg) or cardiogenic shock, sick sinus syndrome (if no pacemaker is present), 2nd- or 3rd-degree AV block. **Warnings:** ISOPTIN should be avoided in patients with severe left ventricular dysfunction (e.g., ejection fraction <30%) or moderate to severe symptoms of cardiac failure. Control milder heart failure with optimum digitalization and/or diuretics before ISOPTIN is used. ISOPTIN may occasionally produce hypotension (usually asymptomatic, orthostatic, mild, and controlled by decrease in ISOPTIN dose). Occasional elevations of liver enzymes have been reported; patients receiving ISOPTIN should have liver enzymes monitored periodically. Patients with atrial flutter/fibrillation and an accessory AV pathway (e.g., W-P-W or L-G-L syndromes) may develop a very rapid ventricular response after receiving ISOPTIN (or digitalis). Treatment is usually D.C.-cardioversion. AV block may occur (3rd degree, 0.8%). Development of marked 1st-degree block or progression to 2nd- or 3rd-degree block requires reduction in dosage or, rarely, discontinuation and institution of appropriate therapy. Sinus bradycardia, 2nd-degree AV block, sinus arrest, pulmonary edema, and/or severe hypotension were seen in some critically ill patients with hypertrophic cardiomyopathy who were treated with ISOPTIN. **Precautions:** ISOPTIN should be given cautiously to patients with impaired hepatic function (in severe dysfunction use about 30% of the normal dose) or impaired renal function, and patients should be monitored for abnormal prolongation of the PR interval or other signs of overdosage. Studies in a small number of patients suggest that concomitant use of ISOPTIN and beta blockers may be beneficial in patients with chronic stable angina. Combined therapy can also have adverse effects on cardiac function. Therefore, until further studies are completed, ISOPTIN should be used alone, if possible. If combined therapy is used, patients should be monitored closely. Combined therapy with ISOPTIN and propranolol should usually be avoided in patients with AV conduction abnormalities and/or depressed left ventricular function or in patients who have also recently received methyldopa. Chronic ISOPTIN treatment increases serum digoxin levels by 50% to 70% during the first week of therapy, which can result in digitalis toxicity. The digoxin dose should be reduced when ISOPTIN is given, and the patient carefully monitored. ISOPTIN may have an additive hypotensive effect in patients receiving blood-pressure-lowering agents. Disopyramide should not be given within 48 hours before or 24 hours after ISOPTIN administration. Until further data are obtained, combined ISOPTIN and quinidine therapy in patients with hypertrophic cardiomyopathy should probably be avoided, since significant hypotension may result. Adequate animal carcinogenicity studies have not been performed. One study in rats did not suggest a tumorigenic potential, and verapamil was not mutagenic in the Ames test. *Pregnancy Category C:* There are no adequate and well-controlled studies in pregnant women. This drug should be used during pregnancy, labor, and delivery only if clearly needed. It is not known whether verapamil is excreted in breast milk; therefore, nursing should be discontinued during ISOPTIN use. **Adverse Reactions:** Hypotension (2.9%), peripheral edema (1.7%), AV block: 3rd degree (0.8%), bradycardia: HR<50/min (1.1%), CHF or pulmonary edema (0.9%), dizziness (3.6%), headache (1.8%), fatigue (1.1%), constipation (6.3%), nausea (1.6%). The following reactions, reported in less than 0.5%, occurred under circumstances where a causal relationship is not certain: confusion, paresthesia, insomnia, somnolence, equilibrium disorders, blurred vision, syncope, muscle cramps, shakiness, claudication, hair loss, maculae, and spotty menstruation. Overall continuation rate of 94.5% in 1,166 patients. **How Supplied:** ISOPTIN (verapamil HCl) is supplied in 80 mg and 120 mg sugar-coated tablets. July 1982

Clinical Echocardiography

Hemodynamic and Pathological Correlations

by José Missri, MD
0-914316-41-9, 282 pages, 173 illus., Oct. '84, $45.00

Dr. Missri has produced a unique contribution to the further understanding and application of Doppler echocardiography in the clinical practice of medicine. This book provides the reader with ready access to a body of knowledge so logically and clearly presented that its practical utility is undeniable. Enhanced by 139 halftones, 16 line drawings and 18 tables, the information contained within its concise 282 pages is easily absorbed. And the 315 references cited not only support the material presented but serve as an excellent guide to anyone interested in further in-depth reading.

Influence of Magnesium Ion on Human Ventricular Defibrillation After Aortocoronary Bypass Surgery

BERNICE R. HECKER, MD, CAROL L. LAKE, MD, IRVING L. KRON, MD, ROBERT M. MENTZER, MD, IVAN K. CROSBY, MD, STANTON P. NOLAN, MD, and RICHARD S. CRAMPTON, MD

The administration of magnesium ion (Mg^{++}) has been reported to defibrillate the ventricles and to decrease the incidence of arrhythmias after cardiopulmonary bypass. In a prospective study of 76 randomly selected patients undergoing coronary artery bypass grafting, patients received either no Mg^{++}, 0.25 mEq/kg of Mg^{++} during cardiopulmonary bypass with the aorta clamped, or 0.375 mEq/kg of Mg^{++} before cardiopulmonary bypass. Spontaneous resumption of a cardiac rhythm or spontaneous defibrillation during reperfusion was not significantly affected by Mg^{++} administration. However, the number of shocks to initial and to sustained defibrillation and the energy required for the last direct-current shock was greatest in patients who received Mg^{++} before bypass and in those whose plasma Mg^{++} was greater than 2.26 mg/dl. Thus, the administration of Mg^{++} may have adverse effects on the heart if intraoperative plasma Mg^{++} exceeds 2.26 mg/dl.

(Am J Cardiol 1985;55:61–64)

Techniques or interventions augmenting spontaneous resumption of cardiac electrical activity rather than permitting the onset or persistence of ventricular fibrillation (VF) during reperfusion are desirable for preventing myocardial injury from the energy or current of direct-current shocks.[1,2]

Magnesium ion (Mg^{++}), which is often abnormally low in patients preoperatively or during cardiopulmonary bypass,[3–6] stabilizes membrane conductance preserving ionic gradients, maintains a steady resting potential and normalizes cellular electrical responses.[7–9] During cardiac surgery,[3,9,13] cardiac arrhythmias[7,10] or acute myocardial infarction,[11,12] an increase in the frequency of spontaneous defibrillation[13] and a decrease in the occurrence of arrhythmias have been noted after the administration of Mg^{++} salts.[7–12] We related the effects of administration of Mg^{++} to spontaneous cardiac electrical activity at the time of reperfusion, to energy, current, resistance of shocks to defibrillate and to the number of shocks required to defibrillate patients undergoing coronary bypass grafting.

From the Departments of Anesthesiology, Surgery (Thoracic and Cardiovascular), and Internal Medicine (Cardiology), University of Virginia Medical Center, Charlottesville, Virginia. This study was supported by the American Heart Association, Virginia Affiliate, Richmond, Virginia. Manuscript received June 1, 1984; revised manuscript received August 29, 1984, accepted August 31, 1984.

Address for reprints: Carol L. Lake, MD, Department of Anesthesiology, Box 238, University of Virginia Medical Center, Charlottesville, Virginia 22908.

Methods

This study was performed between July 1982 and June 1983 on a randomly selected population of 76 patients who underwent coronary artery bypass grafting and who did not have a history of arrhythmias or a need for antiarrhythmic drugs. No patient had congestive heart failure or an ejection fraction less than 0.5.

Anesthetic and surgical techniques were consistent throughout the period of study. Before the induction of anesthesia, a blood sample was obtained for determination of plasma Mg^{++}. Normal values were 1.8 to 2.8 mg/dl. The patient population was prospectively classified into 3 groups. Group I received no supplemental Mg^{++}; group II received Mg^{++}, 0.25 mEq/kg body weight as sulfate, intravenously during cardiopulmonary bypass with the aorta clamped; group III received Mg^{++}, 0.375 mEq/kg as sulfate, intravenously before cardiopulmonary bypass. At the time of reperfusion, 3 types of electrical events occurred: reperfusion electrical activity, defined as any nonfibrillatory rhythm including ventricular asystole; spontaneous defibrillation defined as VF that terminated spontaneously; and primary VF, defined as VF that requried direct-current shock. At the time of spontaneous electrical activity or defibrillation or before and after direct-current shocks, the following variables were measured: (1) plasma Mg^{++} levels, using atomic absorption spectrophotometry; (2) plasma ionized calcium levels, using the Orion SS20 analyzer; (3) plasma potassium levels, using a Nova Biomedical direct potentiometer; (4) arterial P_{O_2}, P_{CO_2} and pH, using standard electrodes and corrected to the patient's perfusion temperature; (5) plasma norepinephrine and epinephrine levels, using high-performance liquid chromatography; (6) mean systemic, pulmonary and coronary perfusion

TABLE I Differences Among Groups Receiving Magnesium*

Variable (Mean ± SD)	Group I Control (n = 24)	Group II Mg^{++} During Bypass (n = 24)	Group III Mg^{++} Before Bypass (n = 24)
Plasma Mg^{++} (mg/dl)	1.4 ± 0.2†,§	2.5 ± 0.3‡	2.3 ± 0.3‡
Time after Mg^{++} Admin. (min)	0 ± 0†,§	47 ± 12‡,§	92 ± 36†,‡
Perfusion temperature (deg C)	38.8 ± 0.8†,§	36.8 ± 3.7‡	38.2 ± 1.0†,‡
Ventricular thickness (cm)	0.9 ± 0.2†	0.8 ± 0.2‡,§	1.0 ± 0.2†

* Data from 4 patients excluded because of excessive cardioplegia or enlarged heart.

† $p < 0.05$ compared with values in group II; ‡ $p < 0.05$ compared with values in group I; § $p < 0.05$ compared with values in group III.

Admin. = administration; deg C = degrees centigrade; Mg^{++} = magnesium ion; SD = standard deviation.

pressures, using Bentley Trantec transducers and Hewlett-Packard pressure modules with systemic vascular resistance calculated using the standard formula; (7) myocardial temperature, using a Wilton Webster (NTM-100) probe; (8) perfusion temperature, using an in-line thermistor. The duration of cardiopulmonary bypass, myocardial ischemia, reperfusion, and time from Mg^{++} administration to event were noted. One patient who received Mg^{++} less than 15 minutes before aortic unclamping was excluded.

Direct-current shocks were administered using a Physio Control Series 640 defibrillator, delivering between 0 and 320 J. An initial shock of 1 J was given. If needed, a second shock at 2.5 J was given. Thereafter, energy was increased by 2.5-J increments until defibrillation. If a shock succeeded, but the heart refibrillated, the next shock was given at the last successful energy. Current was measured with a Tektronix P6303 current probe and amplifier. Resistance was determined from calibration curves of energy and current created by discharging the defibrillator into known loads.

Instillation of high-potassium cardioplegia was performed whenever myocardial septal temperature was above 18°C or cardiac electromechanical activity was noted. Cardioplegic solution consisted of potassium chloride, 26 mEq, 50% dextrose, 27 ml, sodium hydroxide, 1N, 0.15 ml in 1 liter of lactated Ringer's solution cooled to 4°C. When only myocardial cooling was necessary, Polyonic®, an electrolyte solution that contains potassium, 4 mEq/liter, and magnesium, 3 mEq/liter, was instilled. The adequacy of myocardial preservation was assessed by noting the type and volume of cardioplegic solution administered, use of topical hypothermia and duration of myocardial temperature less than 18°C. Two patients who received more than 1,900 ml of cardioplegic solution were excluded from group III.

At cardiac catheterization, biplane cineangiograms were recorded on 35-mm film in the right and left anterior oblique positions. The area-length method was used to calculate end-diastolic volume. Wall thickness was measured halfway between the equator and the base of the heart at end-diastole. Mass was then calculated using the method of Rackley et al[14] and Wynne et al.[15] Two patients with estimated heart weights of more than 300 g, 1 from group III and 1 from group I, were excluded.

All data are expressed as mean ± standard deviation and were stored on a PDP 1144 computer. Statistical analyses were performed by the Statistical Analysis System (SAS Circle) using general linear modeling, Duncan's multiple-range, chi-square, Fisher's 1- and 2-tailed tests, or Student *t* test.

TABLE II Overall Outcome Characteristics

Cardiac Activity (Unclamping)	Group I (n = 24) Control	Group II (n = 24) Mg^{++} During Bypass	Group III (n = 24) Mg^{++} Before Bypass
Reperfusion electrical activity	19	22	18
Developed fibrillation during reperfusion	13	19	14
Spontaneous defibrillation	2	0	0
Direct-current shocks	3	2	6

Mg^{++} = magnesium ion.

Comparisons of spontaneous electrical events after reperfusion, success or failure of direct-current shock, and energy, current and resistance of defibrillation, were made among and across groups. Data were analyzed across groups for selected plasma Mg^{++} and selected plasma Mg^{++} associated with time of administration (i.e., before or during bypass). Plasma Mg^{++} levels above and below 2.26 mg/dl were arbitrarily chosen to provide sufficient number of patients for statistical analyses at higher and lower Mg^{++} levels. This resulted in separation of the patient population into 5 groups. Patients in group A received no Mg^{++}. Patients in group B received Mg^{++} during bypass and had Mg^{++} levels that exceeded 2.26 mg/dl. Patients in group C received Mg^{++} during bypass levels of less than 2.26 mg/dl. Patients in group D received Mg^{++} before bypass and had Mg^{++} levels of greater than 2.26 mg/dl. Patients in group E received Mg^{++} before bypass, but had Mg^{++} levels of less than 2.26 mg/dl. In summary, 4 patients were eliminated from the study for excessive cardioplegic volume (n = 2) and enlarged heart (n = 2).

Results

The mean control Mg^{++} level was 2.02 ± 0.19 mg/dl (range 1.45 to 2.48) in the 72 patients in the study before the induction of anesthesia. Four patients in group I, 1 in group II and 2 in group III had hypomagnesemia (<1.8 mg/dl). The plasma Mg^{++} concentration decreased to 1.4 ± 0.2 mg/dl ($p = 0.0001$) in control patients who did not receive intraoperative Mg^{++}, whereas it increased significantly in patients in group II (2.5 ± 0.3 mg/dl, $p = 0.0001$) and group III (2.3 ± 0.3 mg/dl, $p = 0.0001$) (Table I). Significant differences were found in 3 other variables (Table I). The time from onset of administration of Mg^{++} to the sampling for the study was longest in group III. The perfusion temperature was higher in groups I and III than in group II. Left ventricular thickness was greatest in group III (Table I). Patients in groups II and III received slightly more cardioplegia containing Mg^{++} than those in group I, although the difference was not statistically significant.

The prevalence of VF on reperfusion and the occurrence and type of other dysrhythmias were similar in all 3 groups (Table II). Spontaneous defibrillation occurred in 2 control patients (group I) and in none of the patients treated with Mg^{++}, as the initial reperfusion event. However, the incidence of reperfusion VF was highest in group III (35%) and lowest in group II (18%) (Table II). No significant differences in the incidence of spontaneous resumption of electrical activity or energy and current required to defibrillate were seen as

a result of Mg^{++} administration alone. However, group III patients required more shocks to the first defibrillation (3.1 ± 1.8 vs 2.2 ± 1.0) than group II patients. Although not significant, group III patients also required the greatest number of shocks to sustained defibrillation. Development of VF after initial spontaneous electrical activity occurred frequently in all patients, although group I, which included patients who received no supplemental Mg^{++}, had the lowest incidence of fibrillation—68%, compared with 86% in group II and 78% in group III. Atrial or ventricular arrhythmias after discontinuation of bypass were seen more often in group III than in group I. Other events after bypass or after operation, such as death, ventricular failure, or need for antiarrhythmic, inotropic or vasodilator drugs, occurred so infrequently as to preclude valid statistical analysis.

The relation of plasma Mg^{++} concentration and time of administration of Mg^{++} to spontaneous electrical activity after aortic unclamping, number of direct-current shocks and levels of energy, current and resistance were also investigated. When plasma Mg^{++} was greater than 2.26 mg/dl (group D), higher levels of energy were needed to defibrillate (Table III). The number of shocks necessary for initial and sustained defibrillation in patients with a serum Mg^{++} level of more than 2.26 mg/dl who received Mg^{++} before bypass (group D) was greater than that in any other groups (Table III). The energy required for sustained defibrillation tended to be greater in this group (Table III).

Discussion

Magnesium ion influences cardiac automaticity, excitability, VF threshold, conduction and contractility. Ventricular tachycardia and VF, coronary spasm and supraventricular arrhythmias occur with hypomagnesemia,[12] particularly with digitalis toxicity.[7–12] Magnesium treatment is effective even in hypokalemia.[7] Patients who undergo open-heart surgery with cardiopulmonary bypass have low serum Mg^{++} levels during the perioperative period.[3–5] Büky[13] gave intravenous Mg^{++}, 0.1 mg/kg, during reperfusion. Spontaneous defibrillation was noted within minutes in 18 of 27 patients and facilitation of defibrillation was noted in the remaining patients. Krasner et al[9] documented a decrease in the QTc interval in patients who received sufficient oral magnesium preoperatively to normalize serum Mg^{++} levels. Such a decrease in the QTc interval would be expected to reduce vulnerability to ventricular arrhythmias if this interval had been lengthened by an arrhythmogenic mechanism such as hypomagnesemia or hypokalemia. Intravenous Mg^{++} terminated torsades de pointes in normal patients with prolonged QTc intervals.[16]

When Mg^{++} was infused as a component of cardioplegic solutions, a decrease in arrhythmias and an increase in cardiac contractility occurred after reperfusion.[17–19] However, some investigators found undesirable effects of intracoronary administration of Mg^{++}.[18–20] When cardioplegic solutions contained more than 15 m*M*/liter (360 mg/liter) of Mg^{++}, Hearse et al[18] observed lower aortic pressure, flow and heart rate on reperfusion of isolated rat hearts. When Shapira et al[20]

compared patients with potassium or blood cardioplegia with those receiving Mg^{++} cardioplegia, they found depression of maximal contractile element velocity and increased left ventricular end-diastolic pressure in the group treated with Mg^{++}. No differences in the incidence of postoperative cardiac failure could be attributed to the Mg^{++} content or volume of cardioplegia solution administered to our patients.

In our study, significant differences appeared in plasma Mg^{++}, time from administration of Mg^{++} to cardiac event, perfusion temperature and left ventricular thickness. Neither of the latter 2 variables is known to affect spontaneous defibrillation, requirements for levels of energy or current, or success of direct-current shocks.[21] Our results then, may be attributed to the serum Mg^{++} level or the duration of myocardial exposure to Mg^{++}.

Although our observations differ from those in several reports,[10–13] they are not unexpected. Calcium entry into myocardial cells is competitively antagonized by Mg^{++},[8] yet electrical stability depends on adequate extracellular concentrations of both calcium and Mg^{++}.[24] Slow channel sodium influx and cardiac automaticity, cardiac excitability, the velocity of atrial and ventricular conduction, and the development of ventricular tension—all processes dependent on the flow of calcium ion into myocardial cells—are depressed by administration of Mg^{++}.[7,10,22,23] The reduction in spontaneous resumption of cardiac rhythm seen in our patients and in those of Shapira et al[20] may be due to a relative excess of Mg^{++} hyperpolarizing the cell membrane. Hyperpolarization of the myocardial cell by elevation of extracellular Mg^{++} would necessitate greater current to depolarize the cell membrane and account for the depression of reperfusion electrical activity. On the other hand, reduction of extracellular Mg^{++} partially depolarizes the cell and causes arrhythmias.[25] By decreasing potassium conductance, Mg^{++} maintains a more negative potential across the cell membrane.[7,8,10,12]

Variation of our findings from those of previous investigators needs explanation. First, Büky's[13] study was performed using ischemic arrest rather than cardioplegia and topical hypothermia for myocardial preservation. Second, the effects of Mg^{++} on ischemic fibrillating hearts[26] may well differ from hearts subjected to current myocardial preservation techniques.[18] Third, we correlated our results with the serum Mg^{++} attained rather than with the dose of Mg^{++} administered alone. Serum Mg^{++} levels observed in our patients may correspond to higher extracellular Mg^{++} levels than those reached in other studies. Also, serum Mg^{++} in our patients was more acutely achieved, allowing little time for equilibration compared with oral administration. Fourth, although this was an unblinded study, criteria for patient inclusion, anesthetic and intraoperative management, and surgical technique were unchanged during the 12 months of study, so that differences among groups, except by chance, seemed unlikely. Finally, because earlier investigators did not eliminate or control other variables affecting myocardial activity and defibrillation, such as myocardial temperature or serum potassium concentration,[21] their results differed from ours.

Conclusion: We found that administration of intravenous Mg^{++} to attain normal plasma levels did not facilitate ventricular defibrillation. Moreover, if Mg^{++} is given before cardiopulmonary bypass, more direct-current shocks of higher energy levels are needed to defibrillate. With current myocardial preservation techniques, the prophylactic administration of intravenous Mg^{++} before cardiopulmonary bypass may have adverse effects on the heart when attained plasma levels exceed the midnormal range.

Remnant Saphenous Veins After Aortocoronary Bypass Grafting: Analysis of 3,394 Centimeters of Unused Vein from 402 Patients

BRUCE F. WALLER, MD, and WILLIAM C. ROBERTS, MD

To assess the status of a saphenous vein (SV) excised for coronary artery bypass grafting (CABG), 3,394 cm of remnant SV from 402 patients who underwent CABG were examined. The SV remnants were 0.5 to 52 cm long (mean 8.4). They were sectioned into 5-mm-long segments, and the resulting 6,788 five-millimeter segments were examined histologically: 5,896 (87%) were narrowed 0 to 25% in cross-sectional area by fibrous tissue; 853 (12%) were narrowed 26 to 50%; 23 (0.6%), 51 to 75%, and 16 (0.4%) segments were narrowed 76 to 100%. Of the 16 segments severely narrowed, 7 (44%) were nearly totally occluded by fibrous tissue. In 17 patients who died within 24 hours of CABG, similar degrees of luminal narrowing were observed in remnant segments and in utilized segments of SV. Thus, significant preexisting luminal narrowing of SV used for CABG is infrequent. The intimal fibrous thickening is variable within the same vein when each 5-mm-long segment is analyzed; it is variable from 1 vein to another in the same patient, and it varies among patients.

(Am J Cardiol 1985;55:65–71)

Many studies describing early and late morphologic changes occurring in the saphenous vein (SV) used for coronary artery bypass grafting (CABG) have been published.[1–17] Little attention has been focused, however, on the status of the excised SV not used for CABG.[18–20] This study describes morphologic findings in remnant portions of excised SV from 402 patients who underwent CABG.

Methods

Veins studied: Remnants of operatively excised SVs were examined from 402 patients who underwent CABG at the National Heart, Lung, and Blood Institute between January 1972 and December 1981. At the time of CABG, the SV to be used for bypass grafting was isolated between the ankle and knee or thigh or both areas from 1 or both legs. After attached veins were ligated, the SV was removed and washed with heparinized saline solution. All unused segments of SV were submitted for gross and histologic examination. The submitted remnant SV was not simply discarded portions of abnormal SV, but represented all unused segments of SV. The length of the unused segment was measured (in centimeters) and the entire SV remnant was sectioned into 5-mm-long segments (Fig. 1 and 2). The segments were dehydrated, embedded in paraffin, sectioned and stained by the Movat pentachrome method. The percent of cross-sectional area (XSA) luminal narrowing of each SV segment was graded histologically, after magnification to about 40 times, into 4 categories: 0 to 25, 26 to 50, 51 to 75 and 76 to 100 (Fig. 1, 3 and 4). The internal elastic membrane was considered the normal outer rim of the lumen. A total of 3,394 cm of remnant SV were examined (Table I).

Patients: The 402 patients were 34 to 75 years old (mean 56): 16 (4%) were 34 to 40; 77 (19%) were 41 to 50; 184 (46%) were 51 to 60; 115 (29%) were 61 to 70; and 10 (2%) were 71 to 80 (Table I). Of the 402 patients, 337 (84%) were men, from whom 2,789 (82%) cm of remnant SV were examined. No patient had previous CABG, a known history of phlebitis or other diseases of the leg veins, and none had preoperative venograms.

Comparison of unused segments of saphenous vein with segments used as aortocoronary bypass grafts: Of the 402 patients who underwent CABG, 17 (4%) died within 24 hours of operation, and a necropsy was performed (Table II). Of these 17 patients, 13 (76%) could not be separated from the bypass pump, 1 died 6 hours and 3 died 24 hours after operation. These 17 patients had 327 cm of aortocoronary SV bypass conduit available for comparison with 169 cm of their respective SV remnants (Table II). The 17 necropsy patients were of similar age (34 to 68 years, mean 54) and sex (12 men, 71%) to the remaining 385 living patients. The percent of 5-mm segments of SV narrowed to various degrees was similar in 654 SV segments from bypass grafts compared with 338 SV segments from submitted remnants: 0 to 25%: graft = 94%,

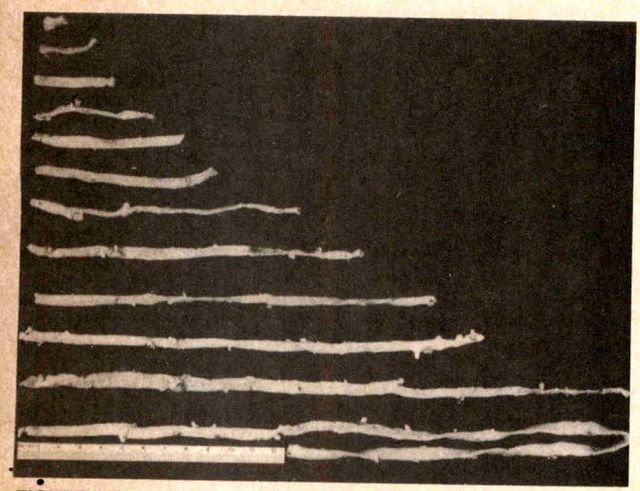

FIGURE 2. Twelve saphenous vein remnants showing the wide range in specimen lengths. The remnants in these 12 patients were 1 to 52 cm long.

remnant = 92%; 26 to 50%: graft = 6%, remnant = 8%; 51 to 100%: graft and remnant = 0 (Table II).

Histology of normal saphenous vein: The wall of the human SV contains a thin intima, separated from media by a rudimentary, fragmented internal elastic membrane. The media consists of 2 layers of smooth muscle cells: an internal longitudinal layer mixed with bundles of collagen and an external circular layer. The adventitia is composed of bundles of collagen, scattered foci of smooth muscle cells and vasa vasorum. At the insertion of venous valves, the medial longitudinal layer usually is thickened.

Results

Remnant length: The SV remnants were from 0.5 to 52 cm long (mean 8.4) (Table I, Fig. 2). The average length of unused portions of SV was similar in men (8.3 cm) and women (9.3 cm), and in younger (50 years or younger [8.8 cm]) and older (older than 50 years [8.4 cm]) patients.

Degrees of cross-sectional area luminal narrowing: SV luminal narrowing consisted of various degrees of intimal fibrous thickening composed of acellular connective tissue. The amount of luminal XSA narrowing in 6,788 five-millimeter SV segments graded histologically was: 0 to 25% XSA = 5,896 (87%) segments; 26 to 50% = 853 (12%); 51 to 75% = 23 (0.6%); and 76 to 100% = 16 (0.4%) segments (Table I, Fig. 3 to 6). Of 5,896 segments narrowed 0 to 25% in XSA by fibrous tissue, only 649 (11%) segments were narrowed to 0 to 5% (i.e., virtually normal). Of 16 segments (from 10 patients) narrowed 76 to 100% in XSA, 7 (44%) segments (from 7 patients) were narrowed 95 to 100% (i.e., virtually occluded) (Fig. 4D, 5 and 7).

Relation of amounts of saphenous vein intimal thickening to sex: The relation between various amounts of XSA narrowing and sex is summarized in Table I and Figure 8. Of 5,578 SV segments from 337 men, 13 (0.5%) segments were narrowed 76 to 100% in

L = length; Seg = segments; SV = saphenous vein; XSA = cross-sectional area.

XSA, 18 (0.5%) were narrowed 51 to 75%, and 5,547 (99%) segments were narrowed 0 to 50%. Similarly, of 1,210 SV segments from 65 women, 3 (0.4%) segments were narrowed 76 to 100% in XSA, 5 (0.6%) were narrowed 51 to 75%, and 1,202 (99%) were narrowed 0 to 50% (Fig. 8). Significant differences in amounts of XSA narrowing between men and women occurred only in the 0 to 50% category. Compared with men, women had a significantly greater percent of SV narrowed 26 to 50% in XSA (16 vs 12%), but a significantly lower percent of SV segments narrowed 0 to 25% in XSA ($p < 0.05$) (Fig. 8).

Relation of amounts of saphenous vein narrowing to age: The relation between patient age and various

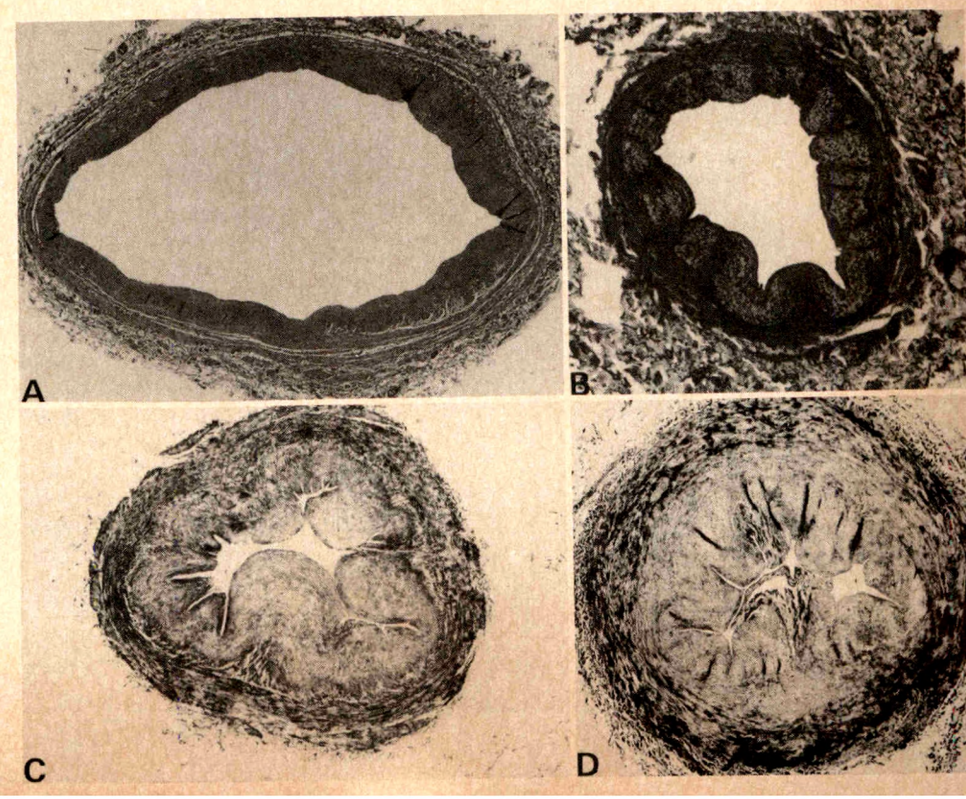

FIGURE 4. Photomicrographs of histologic sections of the 4 saphenous vein remnants illustrated in Figure 3. Movat stain.

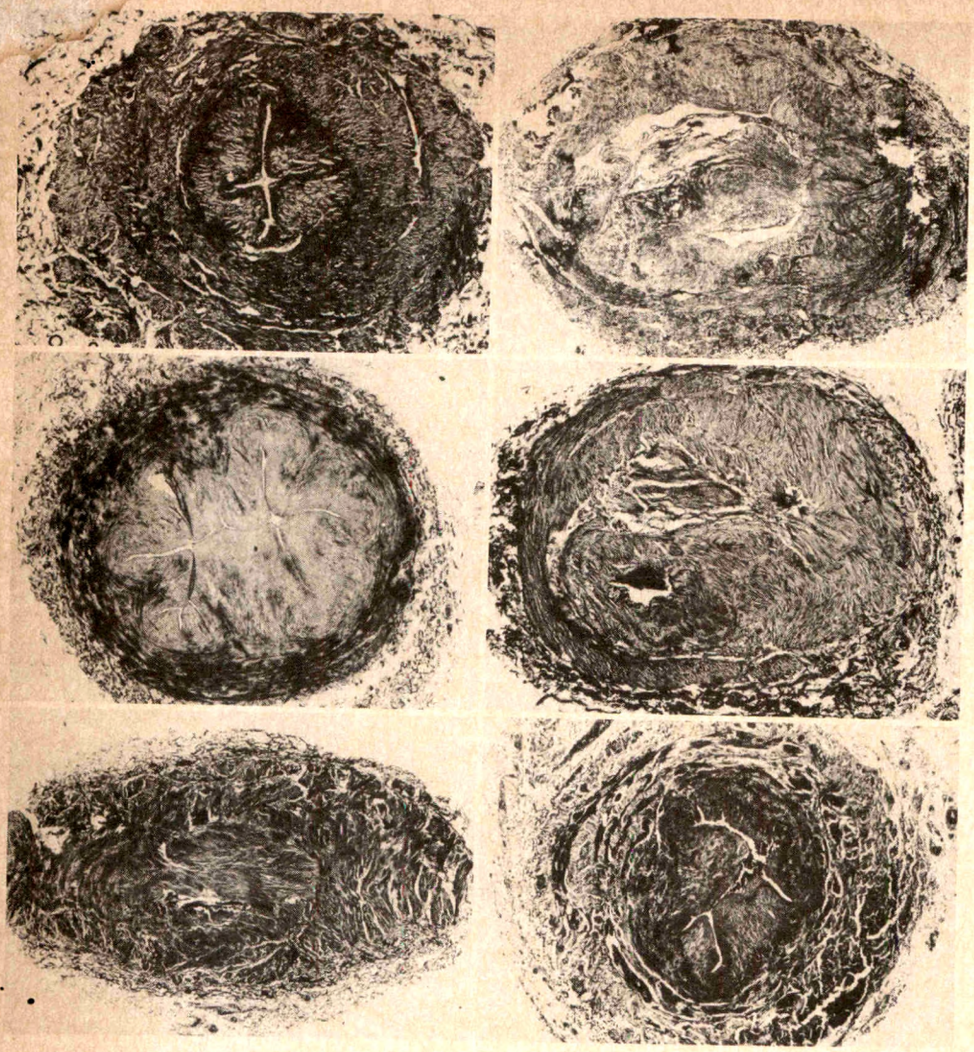

FIGURE 5. Photomicrographs of sites of maximal narrowing in saphenous vein remnants from 6 patients undergoing bypass operation (S79-162, S79-165, S81-63, S81-71, S81-175 and S81-202). All 6 remnants have severe luminal cross-sectional area narrowing by intimal fibrosis. Movat stain.

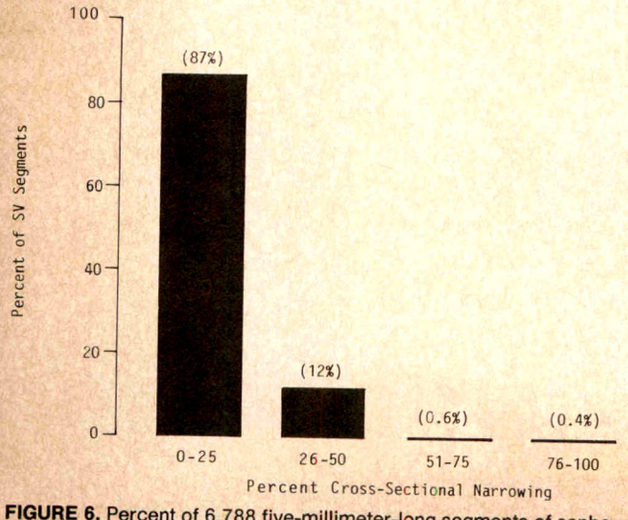

FIGURE 6. Percent of 6,788 five-millimeter-long segments of saphenous vein (SV) remnant from 402 patients undergoing aortocoronary bypass operation, narrowed to various degrees in cross-sectional area by intimal fibrosis.

amounts of luminal XSA narrowing is summarized in Table I and in Figure 9. Of 1,541 SV segments from 93 patients aged 50 years and younger, 8 (0.5%) segments were narrowed 76 to 100% in XSA by intimal fibrous tissue, compared with 8 (0.1%) of 5,247 segments from 309 patients aged older than 50 years. Analysis of luminal narrowing by age decade (Table I, Fig. 9) disclosed a similar frequency of severe (>75% XSA) narrowing between the fourth and seventh decades. No patient in the eighth decade of life had severe (>75% XSA) SV remnant luminal narrowing.

Relation of amount of saphenous vein luminal narrowing to sex and age: Analysis of SV remnants disclosed a similar frequency of severe luminal narrowing in men (7 of 1,392 [0.5%]) and women (1 of 149 [0.7%]) aged 50 years and younger and a similar frequency in men (6 of 4,186 [0.1%]) and women (2 of 1,061 [0.2%]) aged 50 years and older (Fig. 10).

Varicosity of saphenous vein remnants: Of 402 patients, 20 (5%) had focally or diffusely dilated SV remnants. The wall of the SV at sites of dilation were

thinner than normal in 16 patients and thicker than normal in 4 patients.

Discussion

Fibrous thickening of lumens of SV grafts studied early after CABG generally has been regarded as an acquired change rather than as a preexisting preoperative occurrence.[2–5,7] In the present study, analysis of unused portions of operatively excised SV disclosed varying degrees of intimal fibrous thickening in over 90% of SV segments before their use for CABG. Of 402 patients studied, the luminal narrowing was severe (>75% XSA) in 10 patients (16 segments [0.4%]) with near-total occlusion of segments from 7 patients.

Although intimal fibrous thickening is a common finding in the SV used as an aortocoronary conduit for more than 1 month,[2–5,7] considerable variation in amounts of intimal thickening is observed in grafts in

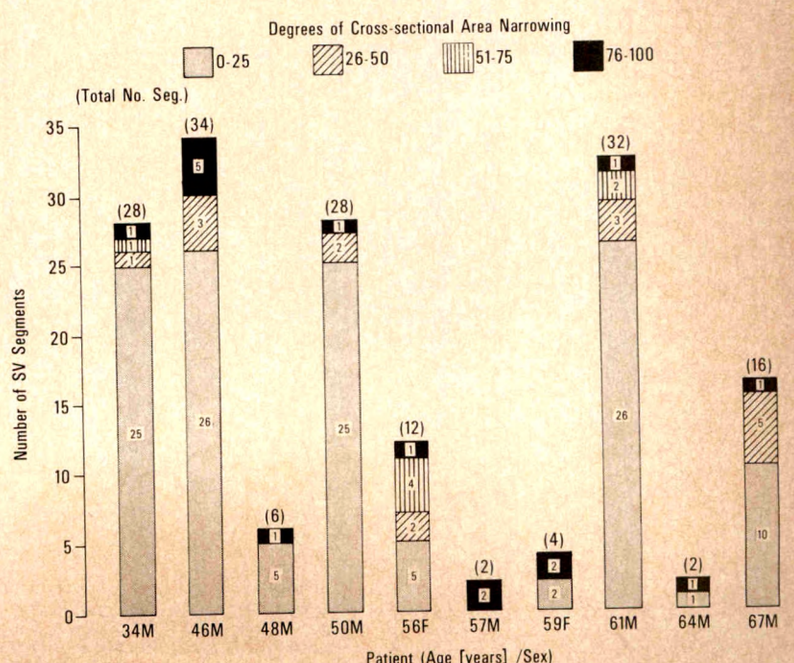

FIGURE 7. The variability in luminal cross-sectional area narrowing within the same saphenous vein (SV) remnant from the 10 patients having at least 1 five-millimeter SV segment (Seg.) narrowed 76 to 100% in cross-sectional area by intimal thickening.

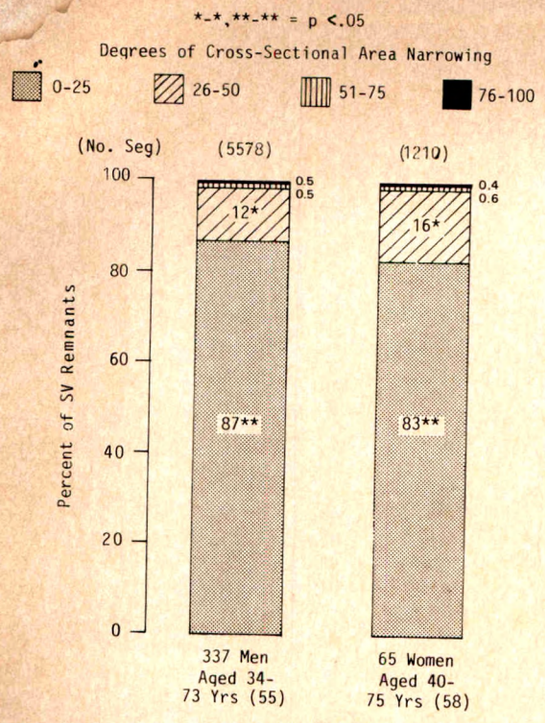

FIGURE 8. Relation between sex and degrees of cross-sectional area luminal narrowing by intimal fibrosis in 6,788 five-millimeter segments (Seg) of saphenous vein (SV) remnant from 337 men and 65 women who underwent aortocoronary bypass grafting.

place for a similar length of time. The variability in degree and extent of the luminal narrowing among different patients has been attributed to such factors as differing systemic arterial pressures,[4] vein damage during SV excision or manipulation before implantation,[21,22] and vein damage from agents used in preparation of the SV for implantation.[23] The high frequency of fibrous thickening in unused SV in the present study, and a similar distribution of these changes in remnant SV segments and their corresponding aortocoronary bypass graft segments suggests that preexisting intimal fibrous thickening may account for some of the variability. Preexisting severe narrowing of the SV used as a conduit of course may impede graft flow.

Two previous studies[18,20] have commented on morphologic changes observed in excised SV intended for use as aortocoronary bypass grafts. Cheanvechai et al[18] examined "representative pieces" of SV not used for grafting procedures from 1,179 patients undergoing CABG. Of 1,179 SV segments, 861 (73%) were "normal" and 318 (27%) were "abnormal." Of the 318 abnormal veins, 280 (88%) were "mildly phlebosclerotic" and 38 (12%) were "moderately sclerotic." Of the 1,170 patients, 391 underwent postoperative conduit angiography 1.5 to 24 months after operation (295 patients with normal SV remnants, 86 patients with abnormal SV remnants); no significant differences were observed in graft patency rates, graft stenoses, or luminal irregularities between the 2 groups. They concluded that the phlebosclerotic vein could be used as a bypass conduit without adverse results. Their study, however, did not define "mild" or "moderate" amounts of phlebosclerosis, and it did not correlate changes in unused (nonimplanted) segments of SV with those in used (implanted) segments.

Thiene et al[20] examined SV from 150 consecutive patients who underwent CABG. Intimal fibrous thickening was observed in 93%, but it was rarely severe enough to narrow the lumen more than 50% (unit not stated). These investigators graded amounts of intimal sclerosis as 1 to 4 with grade 4 representing luminal narrowing greater than 50%. Of 150 veins, 105 (70%) had intimal fibrous thickening but no SV segment had more than 50% luminal narrowing.

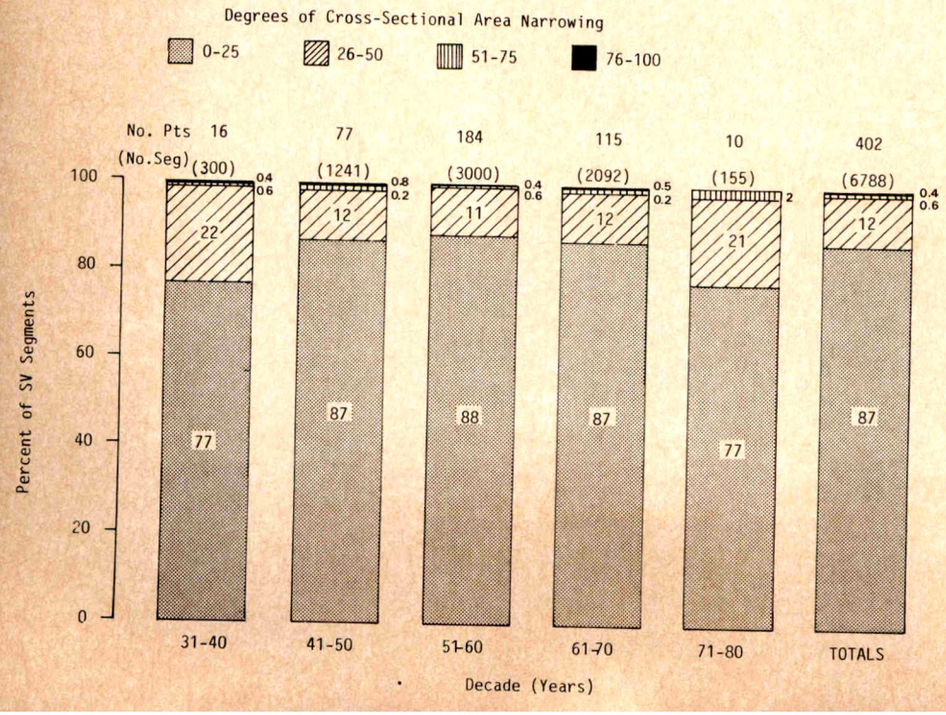

FIGURE 9. Relation between age and degrees of cross-sectional area luminal narrowing by intimal fibrosis in 6,788 five-millimeter segments (Seg) of saphenous vein (SV) remnant from 402 patients aged 31 to 75 years (mean 56) who underwent aortocoronary bypass grafting.

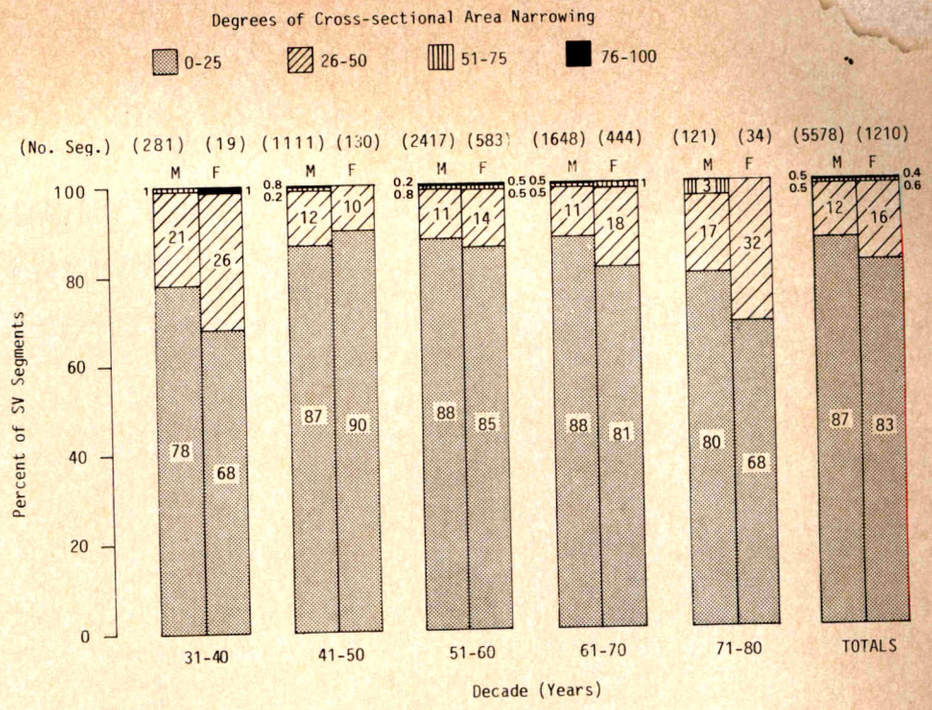

FIGURE 10. Relation between sex, age and degrees of cross-sectional area luminal narrowing by intimal fibrosis in 6,788 five-millimeter segments (Seg.) of saphenous vein (SV) remnants from 402 patients who underwent aorto-coronary bypass grafting.

Saphenous vein intimal fibrous thickening has been stated to increase with advancing age and to occur more frequently in women.[24] In our study and in the study by Thiene et al,[20] age did not correlate with the amount of intimal fibrous thickening. Furthermore, in the present study, severe (>75% XSA) intimal fibrous thickening was similar in both men and women.

About 5% of SV remnants examined in our study had varicoses. Although focal aneurysmal dilation of an implanted aortocoronary SV bypass graft has been reported,[25] its rarity suggests that focal graft aneurysm formation probably represents focal varicoses of the SV present at the time of graft insertion.

Of our 402 patients who underwent CABG, nearly 3,500 cm of SV (about 8.5 cm per patient) was not implanted. The length of unused SV ranged from 0.5 to 52 cm per patient; 45 patients (11%) had at least 15 cm of remnant vein. Repeat CABG is increasing and, correspondingly, the need for additional autogenous bypass graft material is increasing. Perhaps unused excised SV could be "stored" for future use in the same patient, or "denatured" and used as homologous bypass grafts in patients with depleted or diseased SV systems.

Chronic Lorcainide Therapy for Symptomatic Premature Ventricular Complexes: Efficacy, Pharmacokinetics and Evidence for Norlorcainide Antiarrhythmic Effect

R. HARDWIN MEAD, MD, DEBORAH L. KEEFE, MD, ROBERT E. KATES, PhD, and ROGER A. WINKLE, MD

Chronic premature ventricular complexes (PVCs) have been effectively suppressed by oral lorcainide as reported in previous short-term studies. The plasma level-effect relation of lorcainide may be affected by the possible cardioactivity of norlorcainide, a metabolite that accumulates after repeated oral doses. This study evaluated the long-term efficacy of lorcainide in suppressing chronic symptomatic PVCs, and examined the relation of arrhythmia suppression to plasma concentrations of lorcainide and norlorcainide. Fourteen patients were treated with lorcainide, 200 to 400 mg/day, 12 of whom achieved nearly complete suppression of arrhythmias after treatment for 1 year. Chronic lorcainide treatment was well tolerated; no patient discontinued treatment because of adverse effects. Lorcainide and norlorcainide plasma concentrations remained stable after the first week of therapy. Antiarrhythmic activity persisted throughout the year. Upon drug withdrawal, the mean lorcainide washout half-life was 14.3 ± 3.7 hours and the mean norlorcainide washout half-life was 31.9 ± 8.9 hours. The return of arrhythmias occurred well after the lorcainide plasma concentration had decreased to subtherapeutic levels, suggesting an antiarrhythmic effect of norlorcainide. Thus, long-term lorcainide therapy is effective in treating chronic symptomatic PVCs and is well tolerated by most patients. The metabolite norlorcainide appears to have antiarrhythmic activity independent of lorcainide.

(Am J Cardiol 1985;55:72–78)

Lorcainide is a new antiarrhythmic agent undergoing clinical investigation. In vitro studies demonstrate that it is a class I antiarrhythmic agent that decreases phase 0 of the action potential, slows conduction velocity and prolongs the effective refractory period.[1] In clinical trials, lorcainide effectively suppressed chronic ventricular ectopic activity[2–4] and ventricular tachycardia,[6–8] and had a marked negative dromotropic effect on the accessory pathway in patients with Wolff-Parkinson-White syndrome.[5] Intracardiac conduction times and atrial and ventricular refractoriness were prolonged after intravenous or short-term oral loading.[9,10]

Short-term studies have revealed a marked saturable first-pass hepatic metabolism of lorcainide, with accumulation of a metabolite, norlorcainide.[11–13] Bioavailability was low after single, oral, 100-mg doses, but increased with higher doses and approached 100% after several days of multiple oral dosing.[6,11] Norlorcainide accumulated after multiple oral doses, but not after multiple intravenous doses.[11] Within several days of multiple dosing, norlorcainide plasma concentrations exceeded those of lorcainide, and the norlorcainide concentration reached steady state after approximately 1 week of therapy.[14] Norlorcainide has a disappearance half-life of approximately 3 times that of lorcainide after short-term oral therapy, with plasma concentrations more than twice that of the parent compound.[12] The plasma level-effect relation of lorcainide is confounded by the cardioactivity of norlorcainide, which was shown in 1 patient to have antiarrhythmic efficacy; this may explain why some patients have responded to oral but not intravenous lorcainide therapy.[14]

Most studies have focused on the acute or short-term effects of lorcainide. We evaluated the long-term efficacy and patient tolerance of lorcainide in patients with chronic symptomatic ventricular ectopic activity, and correlate suppression of arrhythmias with plasma concentrations of both lorcainide and norlorcainide.

Methods

Patients: Fourteen patients (10 men, 4 women, mean age 55 years) with symptomatic, chronic premature ventricular complexes (PVCs) responsive to lorcainide during short-term evaluation[12] were studied. Patients were excluded if they had myocardial infarction within 3 months, syncope, sustained ventricular tachycardia or a history of ventricular fibrillation, high degrees of atrioventricular or bifascicular block, uncontrolled congestive heart failure, renal or hepatic disease, or uncontrolled systemic hypertension.

Patient characteristics: Three of the 14 patients included in the study had no known structural heart disease; 2 had mitral valve prolapse. Seven patients had known coronary artery disease, 3 with previous myocardial infarctions; 1 patient had hypertensive heart disease without documented coronary disease; and 1 patient had cardiomyopathy due to acromegaly. All patients had poor results with at least 1 conventional antiarrhythmic drug before lorcainide therapy. No patient was taking cimetidine.

Study design: All patients had 2 separate 24-hour ambulatory electrocardiographic (ECG) recordings while not taking antiarrhythmic drugs. All antiarrhythmic medications had been discontinued for at least 5 half-lives to assume adequate washout. No patient had previously received amiodarone. Twenty-four-hour ambulatory ECG recordings were repeated at 1 week, 1 month and 2 months, and then every 2 months, for a total of 12 months. Each patient began therapy with 100 mg orally every 12 hours; the dose was increased as needed based on the results of the ambulatory ECG recordings. After 12 months, the drug was discontinued. Twenty-four-hour outpatient ambulatory ECG recordings were performed continuously during the 10 days after therapy was discontinued. Adverse effects were recorded in detail.

Determination of plasma lorcainide and norlorcainide concentrations: Samples of venous blood (10 ml) were obtained by direct venipuncture, or through an indwelling intravenous catheter, at the beginning of each monitoring period. Plasma was drawn for drug concentration determination during the drug withdrawal period just before the last dose, and then at 1, 2, 3, 4, 6, 8, 10, 12, 24 and 36 hours after cessation of therapy, and then daily for 10 days. These were placed into heparinized screw-cap tubes, centrifuged, and the plasma frozen at −20° C until analyzed. Analysis was performed as previously reported by a high-pressure liquid chromatographic method that detects both lorcainide and its N-dealkylated metabolite, norlorcainide.[15]

Data analysis: Ambulatory electrocardiograms were analyzed by the Stanford computer-assisted method, which gives accurate counts of all ventricular arrhythmias occurring on each recording. Total PVC counts, as well as counts of all pairs and runs, were recorded for the entire 24 hours. Counts were normalized to 24 hours for tapes not exactly 24 hours long.

Mean steady-state lorcainide and norlorcainide levels were determined during the last dosing interval by dividing the area under the plasma-concentration time curve by the duration of the dosing interval. The plasma-concentration time curve was determined by the trapezoidal rule. The disappearance half-lives were determined by linear least-squares fitting of the terminal log-linear portion of the plasma concentration-time curve during the washout period.

Data are presented as mean ± standard deviation, and statistical comparisons of the washout half-life were determined with the Student t test for paired data.

Results

Chronic antiarrhythmic efficacy: Lorcainide was effective for chronically suppressing PVCs in 12 of the 14 patients entered into the study. Patient 5, initially believed to be responding to lorcainide, had severe sleep disturbance and did not have a reduction in his arrhythmias after 1 month of therapy with lorcainide, and was withdrawn from the study. Patient 6 was noncompliant with his medications and was withdrawn at 3 months. Inadequate control of PVCs occurred in patients 4, 10, 11 and 13 while receiving lorcainide, 100 mg twice daily. Increasing the daily dose to between 250 and 400 mg resulted in satisfactory suppression of arrhythmias. The doses taken by each patient are summarized in Table I.

TABLE I Mean Lorcainide and Norlorcainide Steady-State Concentrations 1 Month Through 12 Months

Pt	Dose (mg) (bid)	Lorcainide (ng/ml)	Norlorcainide (ng/ml)

13	200	400 ± 76	1075 ± 263
14	100	74 ± 42	103 ± 38
Mean ± SD		212 ± 129	483 ± 316

* Patient 4 took 100 mg 3 times daily.
Values are mean ± standard deviation.

The 12 patients who completed the study showed a marked reduction in arrhythmias (Fig. 1). No patient had syncope or sustained ventricular tachycardia during the year of therapy. The antiarrhythmic effect of lorcainide persisted in all patients, although patient 9 had an increase in the frequency of arrhythmia during the last month of the study. This patient had a significant increase in his arrhythmias during the washout phase of the study when compared with the period before drug administration, which may account for the apparent diminution in lorcainide efficacy.

Plasma concentration of lorcainide and norlorcainide: The mean plasma concentrations of lorcainide and norlorcainide measured at the time of each ECG monitoring period are listed in Table I. For patients in whom the lorcainide dose was changed during the study period, the values represent the levels obtained when the effective dose had been achieved. The mean plasma lorcainide concentration ranged from 57 to 400 ng/ml (average 212 ± 129) in these patients. The mean plasma norlorcainide concentrations ranged from 103 to 1,075 ng/ml (average 483 ± 316). The mean individual coefficient of variation for the plasma lorcainide concentration in each patient was 32 ± 19%; for norlorcainide it was 27 ± 14%. Coefficients of variation for the mean lorcainide and norlorcainide concentrations for the entire group were 61% and 65%, respectively. The variations in plasma concentration in each patient were thus significantly less than the variation between patients.

Mean steady-state plasma lorcainide and norlorcainide concentrations were determined for 10 patients during 1 dosing interval after 1 year of therapy. The mean plasma lorcainide concentration during this dosing interval ranged from 44 to 287 ng/ml (mean 171 ± 73) and the mean norlorcainide plasma concentration ranged from 103 to 889 ng/ml (mean 387 ± 225). The ratio of norlorcainide to lorcainide varied from 1.1 to 4.1 (average 2.4 ± 1.0). In addition, for the 8 patients who received 100 mg twice daily, there was a strong negative correlation between the concentration of lorcainide and the ratio of norlorcainide to lorcainide ($r = -0.63$).

After 1 year of lorcainide therapy, 12 patients were available to participate in the washout phase, at which time the drug was withheld for 10 days. Patient 13 was fearful of the palpitations that developed from her arrhythmia; therefore, lorcainide was not discontinued. Patient 7 self-administered several lorcainide doses during the washout period, and thus was not included. The half-lives of lorcainide and norlorcainide determined during the washout period in the remaining 10 patients are listed in Table II. The half-life of lorcainide in these patients ranged from 10.7 to 22.7 hours (average 14.3 ± 3.7). Norlorcainide half-lives ranged from 19.2 to 47.7 hours (average 31.9 ± 8.9). In 6 patients, washout half-lives had been determined after only 4.5 days of therapy.[12] For these 6 patients, the lorcainide half-lives varied from 6.2 to 13.5 hours (mean 10.8 ± 2.9) and the norlorcainide half-lives ranged from 19.1 to 37.6 hours (mean 28.9 ± 8.4) at 4.5 days. Although there was no difference in the norlorcainide half-life at 4.5 days and 1 year of therapy, the increase in the lorcainide half-life over the year was significant ($p < 0.05$).

Return of arrhythmias after drug withdrawal: relation to plasma drug concentration: Lorcainide therapy was successfully withdrawn in 10 patients, as previously noted. Tables III and IV show the return of arrhythmias in these patients. In patient 14, arrhythmias did not return during the washout period. In the remaining patients, there was a gradual return of ventricular arrhythmias, with up to 6 days elapsing before 24-hour monitoring revealed a full return of PVCs, pairs and runs. The return of arrhythmias relative to the plasma drug concentrations for patients 1 and 3 is shown in Figures 2 and 3. The lorcainide plasma concentration was below 35 ng/ml by day 3 in all patients except patient 12, in whom it was 76 ng/ml.

Adverse effects: Adverse effects were frequent during chronic lorcainide therapy; all patients reported at least 1 adverse effect during the year. Sleep disturbances were the most common adverse effect, occurring in 9 patients during the first week of treatment and persisting to some extent in 7 patients by the end of 1 year. Four of the 9 patients used flurazepam to minimize the sleep disturbance during the first month of treatment, and 2 of these patients continued to use the medication occasionally after the first 2 months. Gastrointestinal upset, headache, and a sense of anxiety or

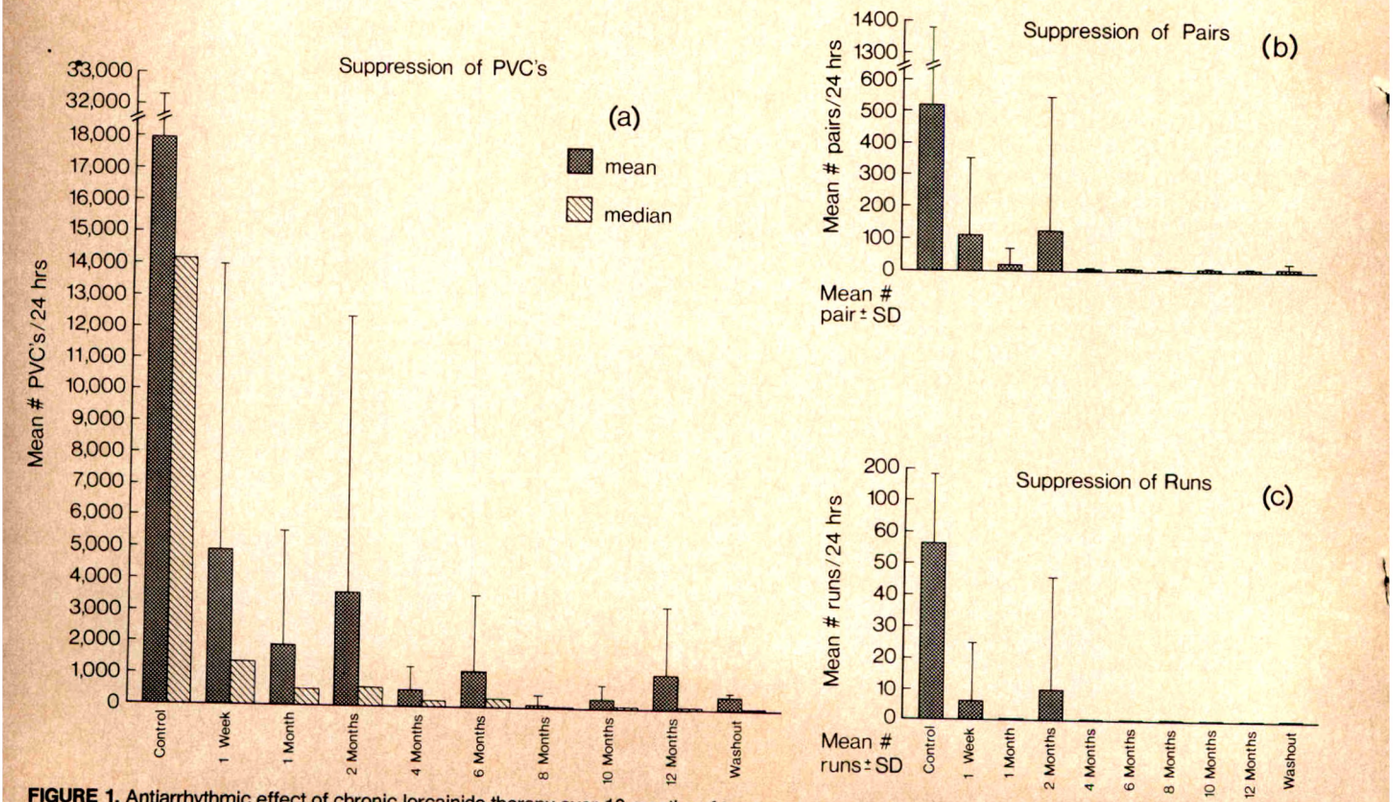

FIGURE 1. Antiarrhythmic effect of chronic lorcainide therapy over 12 months of treatment compared with baseline arrhythmia frequency. Suppression of premature ventricular complexes (PVCs) (**a**), pairs, (**b**) and runs (**c**) persisted during the year of therapy. SD = standard deviation.

tremulousness were also reported by several patients, although these effects subsided during the months of therapy (Table V). Despite the high incidence of adverse effects, no patient was withdrawn from treatment solely because of adverse effects of lorcainide. Patients who reported sleep disturbance did not have daytime somnolence or fatigue, and several reported a sense of increased energy. Four patients reported the new onset of fatigue and sleepiness beginning 2 to 5 days after lorcainide was discontinued, which was unrelated to prior sleep disturbance or flurazepam use. This "rebound hypersomnolence" persisted throughout the withdrawal period in these patients.

Discussion

Previous studies have shown that lorcainide is an effective antiarrhythmic agent in patients with frequent PVCs receiving short-term oral treatment regimens and in double-blind comparison with placebo.[2,3] Myburgh et al[16] showed a sustained antiarrhythmic effect over 6 months in 20 patients after myocardial infarction treated with 200 mg/day of lorcainide. This study demonstrates the long-term efficacy of lorcainide in patients with varying cardiac disorders underlying their frequent ectopy. Dosage adjustments were required in 4 of our patients to attain a complete therapeutic response, but the antiarrhythmic effect persisted over the year of treatment, since arrhythmias returned in all but 1 patient in whom the drug treatment was withdrawn.

With chronic oral lorcainide therapy, the plasma concentration of norlorcainide exceeded that of lorcainide; the average norlorcainide/lorcainide ratio of 2.4 was similar to that reported in short-term oral treatment studies.[12] The negative correlation between the lorcainide concentration and the norlorcainide/lorcainide ratio suggests that those patients with more active first-pass metabolism have lower plasma lorcainide levels and produce relatively higher amounts of norlorcainide. The plasma concentrations measured throughout the year, and the mean steady-state levels, are also in agreement with previous studies,[12,13] and did not change significantly over the year in patients receiving therapy. While a considerable variation occurred in the elimination half-lives of both compounds, the mean lorcainide elimination half-life of 14.3 hours is

longer than reported in other studies and is similar to the 17 hours reported for patients with congestive heart failure.[6,9,12] A significant increase in the lorcainide elimination half-life also occurred in a portion of these patients, when compared with that in the first week of therapy. Lorcainide clearance is highly dependent on hepatic blood flow,[9] and this could explain the prolonged elimination half-life in patients with congestive heart failure. Our patients did not exhibit evidence of heart failure, and this is an unlikely mechanism for the observed increase in elimination half-life. A changing volume of distribution of lorcainide would be unlikely also. In patients in whom the elimination half-life was determined at 4.5 days of treatment, plasma lorcainide concentrations were less than those obtained during the subsequent year of therapy. The mean concentration at 1 week was 82 ± 68 ng/ml for the 4 patients in whom it was determined and who also had lorcainide elimination half-life determined at 1 year. This finding would suggest that the observed increase in elimination half-life is due to a decrease in lorcainide clearance, which may continue to develop after 4.5 days of treatment. The presystemic hepatic clearance of oral lorcainide is saturable,[11] and the change in lorcainide clearance observed here may be due to a prolonged time to saturation of first-pass metabolism. If this is coupled with the long half-life of the drug, more than 4.5 days may be required to achieve an initial steady-state metabolism, which would then explain the apparent change in clearance with long-term oral dosing.

The long elimination half-life of norlorcainide enabled us to examine its antiarrhythmic activity during the washout period, because high norlorcainide concentrations were still present after lorcainide concentrations had fallen below the therapeutic range. Comparison of lorcainide and norlorcainide plasma concentrations with return of arrhythmias strongly suggests an antiarrhythmic effect of norlorcainide in

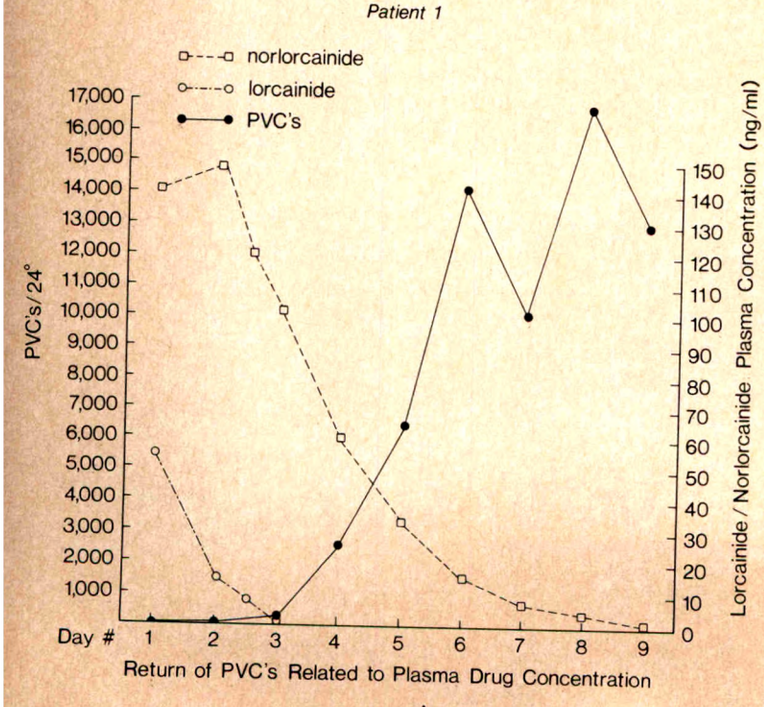

FIGURE 2. Return of premature ventricular complexes (PVCs) during drug washout in patient 1. An antiarrhythmic effect persisted for 4 days after cessation of therapy, when lorcainide plasma concentrations had fallen to subtherapeutic levels.

these patients. Klotz et al[14] reported efficacy of oral lorcainide in 2 patients who did not respond to the intravenous drug, suggesting a contribution of active metabolites to the antiarrhythmic effect. Meinertz et al[13] documented a marked antiarrhythmic effect of norlorcainide infused into 1 patient, in whom plasma concentrations were almost 1,000 ng/ml. The lower plasma lorcainide concentrations that result in effective oral treatment compared with the concentration needed with intravenous lorcainide also support a contribution of norlorcainide to the therapeutic efficacy of the oral drug. A similar observation was made with regard to encainide therapy, in which persistence of antiarrhythmic effect during drug washout suggested significant contribution of 1 or more of its metabolites to antiarrhythmic activity.[17] In this study, plasma levels of lorcainide were well below the previously established minimal effective concentrations of 150 to 400 ng/ml[9] by day 3 of drug washout. Because it is unlikely that these low lorcainide concentrations would be effective in this group, in which the average lorcainide concentrations were more than 200 ng/ml during the year, the persistence of an antiarrhythmic effect 72 hours or longer after the cessation of the drug is strong circumstantial evidence for norlorcainide activity.

The presence of a pharmacologically active metabolite with a long half-life has several therapeutic implications. Atrial and ventricular refractoriness increase, and the AH interval also increases in patients given oral lorcainide after an intravenous infusion.[10] This may reflect a time delay in the distribution of lorcainide to all parts of the myocardium, because much lower plasma concentrations of lorcainide are needed during the postinfusion period to achieve the degree of antiarrhythmic effect seen immediately after the infusion is given.[13] However, the changes seen only with oral lorcainide treatment may also be due to the presence of norlorcainide. Plasma concentrations of both compounds should be determined when drug levels are used to monitor electrophysiologic and antiarrhythmic effects of oral lorcainide. In addition, norlorcainide alone may prove to be a useful antiarrhythmic agent, and further studies to evaluate its actions and adverse effects are warranted. Finally, the persistence of the effect of norlorcainide for several days or longer should be considered if a patient is withdrawn from lorcainide and another antiarrhythmic agent begun.

TABLE V Adverse Effects of Oral Lorcainide Therapy

Adverse Effect	1 Week	6 mo	12 mo	Washout
Sleep disturbance	9	8	7	0
Vivid dreams	5	2	1	0
Inability to sleep	9	7	6	0
Night sweats	2	1	1	0
Anxiety/tremor	3	1	0	1
GI disturbance	5	3	1	0
Headache	3	1	1	0
Sleepiness/fatigue	0	0	1	4

GI = gastrointestinal.

The adverse effects of chronic lorcainide therapy were frequent, and sleep disturbances were the predominant adverse effects, as in previous reports.[2,8,18] We have shown that sleep fragmentation and decrease in total sleep time occurs during oral lorcainide therapy, but that daytime mood and alertness is not consistently affected.[18] Saksena et al[8] reported that in 12 patients with recurrent ventricular tachycardia who were treated

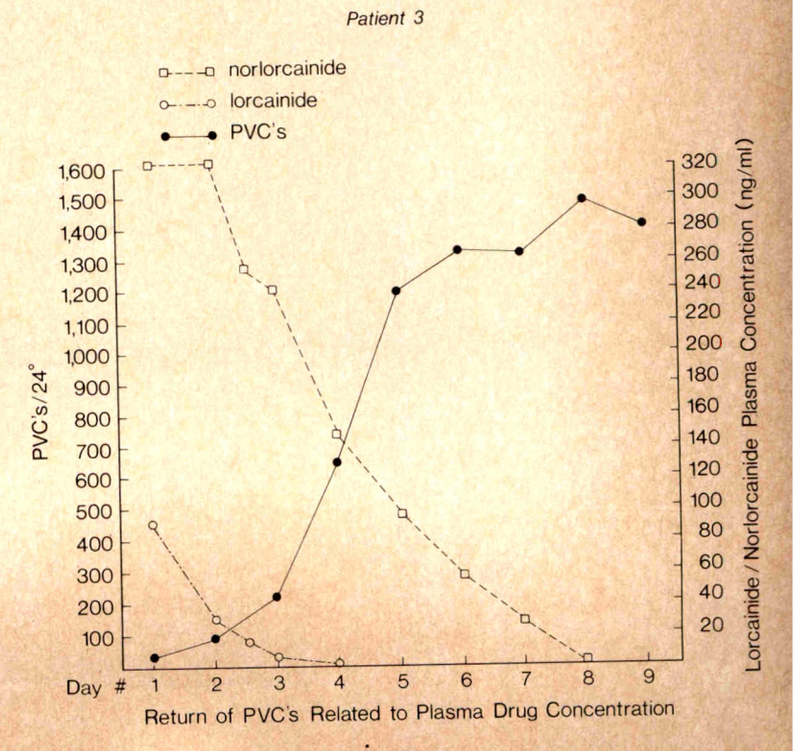

FIGURE 3. Return of premature ventricular beats (PVCs) during drug washout in patient 3. Lorcainide plasma concentration was below 40 ng/ml by day 2, yet ventricular arrhythmias did not return to the baseline frequency until day 5 of washout.

with oral lorcainide, 2 patients had sleep disturbances severe enough to withdraw from the study, and noted that long-term lorcainide therapy was severely limited by adverse effects. This is in contrast to our patients, most of whom had disturbed sleep, but we did not find this effect severe enough to warrant discontinuation of treatment. The "rebound hypersomnolence" observed in several patients on drug withdrawal also suggests the development of tolerance to the sleep disturbance with chronic lorcainide therapy. With the dosages we used, lorcainide was well tolerated in most patients, and therapy was not significantly hampered by its adverse effects.

Flecainide: Long-Term Treatment Using a Reduced Dosing Schedule

DAVID FLOWERS, MD, DEBORAH O'GALLAGHER, RN, VILMA TORRES, MD, DENNIS MIURA, MD, PhD, and JOHN C. SOMBERG, MD

Flecainide was initially prescribed at a dose of 200 mg twice daily, but after early toxicity in patients with ventricular tachycardia (VT), the dosage was reduced to 100 mg twice daily. The effects of flecainide were studied in 40 patients (29 men and 11 women, mean age 62 ± 2 years, ejection fraction 45 ± 3%) who underwent programmed electrical stimulation to determine the efficacy of flecainide in preventing VT chronically at the reduced dose. Sustained VT was induced in 21 patients and nonsustained VT in 19. Flecainide prevented VT induction in 26 patients (65%). At a mean dose of 1.5 ± 0.1 mg/kg, prolongation occurred in the effective refractory period of the first (280 ± 5 vs 249 ± 5 ms) and second (254 ± 6 vs 209 ± 9 ms) extrastimuli ($p < 0.01$). In the patients protected by flecainide, the effective refractory periods increased by a 17 ± 2% and 21 ± 3%, in contrast to only a 7 ± 3% and 6 ± 4% increase in the nonprotected group ($p < 0.05$), despite a higher mean dose (1.9 ± 0.1 vs 1.35 ± 0.1 mg/kg). Twenty-one patients were discharged on flecainide therapy, 100 mg twice daily, and were followed for a mean of 11 months. Sixteen patients are alive and well, 1 died suddenly, 1 died from a noncardiac cause and 1 had a "breakthrough" arrhythmia. Two were switched to quinidine therapy by their referring physicians, but were without problems while receiving flecainide. Thus, flecainide therapy guided by programmed electrical stimulation is effective at a reduced dose.

(Am J Cardiol 1985;55:79–83)

Flecainide acetate is an investigational antiarrhythmic agent developed by Barnitt et al.[1] The efficacy of flecainide for the control of ventricular premature contractions (VPCs) in outpatients has been reported.[2–9] Initial studies have demonstrated the use of flecainide in therapy guided by programmed electrical stimulation and have shown a correlation between acute drug testing with the intravenous form and subsequent protection from ventricular tachycardia (VT) in long-term follow-up.[10,11] In these clinical studies, a total daily oral dose of 300 to 600 mg has usually been given in a twice-daily regimen. Several recent reports have documented various toxic effects of flecainide, including death, that have occurred at these dosing schedules with serum levels ranging from 500 to 2,200 ng/ml.[12–15] Several investigators have suggested that a lower daily dose may be effective, while reducing the incidence of toxicity to a more acceptable level.[15] Forty patients who were referred to the cardiac arrhythmia service for PES-guided therapy because of VT underwent intravenous drug testing with flecainide. We report on the acute drug testing results and long-term follow-up using a reduced dosage regimen of 100 mg of flecainide administered twice daily.

From the Cardiac Arrhythmia Service, Departments of Medicine and Pharmacology, Albert Einstein College of Medicine, Bronx, New York. Manuscript received June 25, 1984; revised manuscript received and accepted August 20, 1984.

Address for reprints: John C. Somberg, MD, Albert Einstein College of Medicine, 1300 Morris Park Avenue, Room 208 Forchheimer Building, Bronx, New York 10461.

Methods

All the patients were admitted to the coronary care unit 36 to 48 hours before PES studies. A baseline electrocardiogram (ECG), Holter ECG, x-ray, urinalysis, hematologic studies and chemistry profiles were performed. Each patient gave informed consent and PES was performed after the patient had discontinued taking all antiarrhythmic drug treatment for at least 5 half-lives.

During all the PES studies, before and after drug administration, surface electrocardiographic leads I, II, aVF and V_5 were continuously monitored, stored on 8-channel magnetic tape and printed on a polygraph recorder along with intracardiac recordings. These data were recorded using a Siemens Elema Mingograf at paper speeds of 25 and 100 mm/s during induction of VT. The intracardiac electrograms were filtered between 50 to 200 Hz and then amplified using a Bloom Associates amplifier.

After PES studies were complete, patients were observed in the coronary care unit for 48 hours and clinical laboratory

TABLE I Comparison of Electrophysiologic Measurements for All Patients Tested with Flecainide

	Mean BP (mm Hg)	HR (beats/min)	PR (ms)	QRS (ms)	QT (ms)	S_2 (ms)	S_3 (ms)
No therapy	94 ± 3	76 ± 3	169 ± 5	94 ± 4	386 ± 7	249 ± 5	208 ± 9
Flecainide (1.5 ± 0.1 mg/kg)	91 ± 3	73 ± 2	190 ± 5*	100 ± 4	400 ± 7	280 ± 5†	254 ± 6†

Significant difference from the group off therapy: * $p < 0.05$; † $p < 0.01$.
BP = blood pressure; HR = heart rate; S_2 = shortest interval from end of the pacing train that the first extrastimulus causes a ventricular depolarization; S_3 = shortest interval between the first and second extrastimulus that causes a ventricular depolarization after the second extrastimulus.

tests, 12-lead ECGs and physical examinations were repeated.

Flecainide was given intravenously by an intermittent bolus of 20 mg every 5 minutes to a dose of 1 mg/kg; the patient then underwent PES. If this dose was not protective, additional boluses were given to a total of 2 mg/kg and testing was repeated. Heart rate, blood pressure, PR, QRS and QT intervals were measured every 5 minutes. Drug administration was terminated if severe nausea or hypotension developed or if QRS or QT intervals were prolonged more than 50% over baseline values. Plasma levels were determined immediately after the PES testing.

PES was performed using a hexapolar pacing catheter introduced through the right internal jugular vein to the apex of the right ventricle. In patients in whom VT could not be induced from the right ventricular apex, the catheter was repositioned to the right ventricular outflow tract. A digital stimulator (Bloom Associates) was used to deliver square-wave electrical impulses of 2.0 ms in duration, with amplitude set at twice diastolic threshold. The right ventricle was driven with a pacing train of 6 beats at a cycle length of 500 ms, with an intertrain interval of 8 seconds.

Single premature ventricular stimuli (S_2) were delivered in late diastole starting at 500 ms from the end of the pacing train and progressively introduced earlier by 20-ms decrements. The shortest interval at which S_2 evoked a depolarization was termed the refractory period. The stimulus was brought out 10 ms further from the end of the pacing train, then a second extrastimulus was introduced at the sum of the S_1S_1 and S_1S_2 intervals and introduced at 20-ms decrements. This programmed introduction of premature stimuli was performed until VT (10 or more beats) was obtained or until 4 premature stimuli were introduced.

Nonsustained VT was defined as at least 10 beats of VT that terminated spontaneously and sustained VT was defined as VT that lasted 30 seconds or required either pacing techniques or defibrillation for termination. A patient was considered protected if 4 stimuli failed to induce more than 3 ventricular beats beyond the last extrastimulus.

Patients: Forty patients underwent electrophysiologic testing to determine if flecainide acetate was an effective antiarrhythmic agent. Twenty-nine were men and 11 were women, mean age 61 ± 2 years. The mean nuclear ejection fraction as determined by nuclear ventriculography performed before flecainide loading was 45 ± 3% (range 25 to 79%). Seven patients presented with a cardiac arrest, 1 patient had syncope with suspected VT as a cause (although not documented on Holter), 20 patients had symptomatic VT (VT associated with syncope, confusion, dizziness, angina or symptoms of congestive heart failure causing presentation at a hospital), and 12 had asymptomatic, nonsustained VT documented on the Holter monitoring. Twenty-nine patients had coronary artery disease, 1 patient had mitral valve prolapse, 2 had dilated cardiomyopathy, and 8 had no apparent structural heart disease detected by routine screening studies. They had failed an average of 1.9 ± 0.2 drugs clinically before being referred to the electrophysiology laboratory, although usually they had received low doses of conventional agents.

Statistical methods: Values are presented as the mean ± the standard error of the mean and were compared using a 1-way analysis of variance for groups and Dunnett's test to differentiate individual means. A Student t test was used to compare values between 2 samples; results were considered significant at the $p < 0.05$ level.

Results

Acute electrophysiologic data: Twenty-one patients had sustained VT and 19 had nonsustained VT provoked during the control electrophysiologic study. Sustained VT was terminated by pacing in 40% of patients and by electrical cardioversion in 60%. Of the total group of 40 patients tested, 26 (65%) were protected by flecainide and in 14 (35%), VT was inducible despite the drug treatment. The electrophysiologic findings are listed in Table I. Patients were given a mean dose of 1.5 ± 0.1 mg/kg of flecainide, which resulted in a plasma level of 230 ± 20 ng/ml. There was a 12% increase in the PR interval ($p < 0.05$) and a 12% and 22% increase in the refractory periods of the first and second extrastimuli, respectively ($p < 0.01$) for all 40 patients tested. Comparing the percent change in refractory periods while receiving the antiarrhythmic agent to the initial determination for each patient, flecainide caused a significant increase in the refractory period of the first and second extrastimuli for the protected patients (17 ± 2% and 21 ± 3%), in contrast to only a 7 ± 3% and 6 ± 4% increase in the nonprotected patients ($p < 0.05$), despite a higher mean dose (1.9 ± 0.1 nonprotected vs 1.35 ± 0.1 mg/kg protected).

Of the 7 patients who presented with a cardiac arrest, 6 (85%) were protected by flecainide and 4 (57%) by procainamide therapy. Sixty-five percent of the patients with symptomatic VT were protected by flecainide and the same number by procainamide therapy. Forty-eight percent of the patients with asymptomatic VT were protected by flecainide at acute drug testing and 57% by procainamide. The 1 patient who presented with syncope of uncertain cause was protected by treatment with both drugs at PES studies.

The number of stimuli required to induce VT and the presenting arrhythmia are listed in Table II. Among patients with what might be considered the greater risk for electrical instability (cardiac arrest), VT was inducible in most cases by 2 stimuli, whereas the symptomatic VT and asymptomatic VT groups were very similar in their pattern of inducibility. With flecainide therapy, the threshold for inducibility was higher in 5

TABLE II Number of Stimuli Required for Induction of Ventricular Tachycardia (VT)

Extrastimuli	1	2	3	4
Cardiac arrest*	0	4 (57%)	1 (14%)	0
Syncope	0	0	1 (100%)	0
Symptomatic VT	1 (5%)	4 (20%)	8 (40%)	7 (35%)
Asymptomatic VT	1 (8%)	1 (8%)	5 (42%)	5 (42%)

* In 2 additional patients VT was induced with ventricular burst pacing.

TABLE IV Electrocardiographic Changes During Chronic Flecainide Therapy

	Off Drug	1 mo.	3 mo.	6 mo.
Heart rate (beats/min)	72 ± 2	74 ± 3	82 ± 3	79 ± 6
PR interval	171 ± 9	194 ± 7	176 ± 11	192 ± 12
QRS interval	81 ± 3	95 ± 7*	102 ± 10*	100 ± 5*
QT interval	369 ± 8	387 ± 7	382 ± 11	387 ± 10

Significant increase from initial value off drug: * $p < 0.05$.

patients, did not change in 2, and was lower in 6. One patient had a clear arrhythmogenic response to the drug: Spontaneous VT developed during the loading period and required defibrillation. The runs of VT subsided within 6 hours after drug administration was terminated.

Comparison with procainamide: Thirty patients were also tested with procainamide as a reference agent. Procainamide was administered intravenously, 100 mg every 5 minutes to a total dose of 1,000 mg, and if this did not provide protection at PES, an additional 500 mg was administered in a similar manner. Procainamide concentration was 7.8 ± 0.4 μg/ml (8.4 ± 0.3 for the protected and 7.2 ± 0.5 for the nonprotected group). Only patients who did not have a clinical event on procainamide or intolerable side effects were studied with this agent in the laboratory. A comparison of the electrophysiologic data only for patients tested with both drugs is given in Table III. In the group of patients tested with both drugs, 63% of the patients tested with flecainide were protected from VT, compared with 60% protected by procainamide.

Long-term follow-up: Of the 26 patients protected by flecainide during the acute electrophysiologic testing, 21 were discharged from the hospital with flecainide therapy. Five of these 21 patients had presented with a cardiac arrest, 11 with symptomatic VT and 5 with asymptomatic VT. All patients initially received 100 mg twice daily and 18 patients were discharged with this dose. In 2 patients the dosage was increased to 100 mg 3 times daily, and in 1 patient to 200 mg twice daily because of inadequate plasma levels (<200 ng/ml) or because of continued high-grade ventricular ectopy. There was an 85% reduction in ventricular ectopic activity and complete abolition of all VT events at these doses. The patients were followed for a mean of 11 ± 1.5 months. During this period, 2 have died: 1 died suddenly (flecainide level—peak 772 ng/ml and trough 644 ng/ml) and 1 died from a noncardiac cause. One patient had several runs of breakthrough VT at a flecainide dose of 100 mg twice daily, with peak serum concentrations of 990 ng/ml and trough of 679 ng/ml. She was switched to high-dose procainamide treatment and has since died. The patient who died suddenly originally presented with asymptomatic VT on Holter, 9 months after a subendocardial myocardial infarction; the patient who had breakthrough arrhythmias originally had had near-syncope from sustained VT. Two patients have been switched to quinidine treatment by their referring physicians because of unease at continuing an experimental drug, despite continued efficacy. Sixteen patients continue to receive flecainide without problems. Thus, of the patients who continued to receive flecainide treatment, 2 of 19 (11%) have had a breakthrough arrhythmia while receiving chronic therapy, although they were protected during acute testing. None of the patients who presented with a cardiac arrest have had recurrent VT or a repeat arrest.

Long-term electrophysiologic data: The PR, QRS, and QT intervals at acute testing and at 1 month, 3 months and 6 months of follow-up are listed in Table IV. Flecainide had no effect on heart rate or PR or QT intervals; however, it did cause a 24% widening of the QRS complex during long-term therapy ($p < 0.05$). No trend toward further widening was noted during follow-up, and there were no apparent clinical complications from the increased QRS interval. Plasma levels of the group that received chronic therapy were 536 ± 77 at 1 month, 525 ± 95 at 3 months and 704 ± 178 at 6 months of follow-up. Four patients have required a gradual reduction in flecainide dosage over several months because of increases in the serum concentration, QRS widening, heart rate slowing, confusion, and dizziness, from 100 mg twice daily to 50 mg 3 times daily or 50 mg twice daily. Despite the smaller daily dosages, the plasma levels have remained between 500 and 700

TABLE III Comparison of Electrophysiologic Measurements for the Groups Not Receiving Antiarrhythmic Therapy

	HR (beats/min)	PR (ms)	QRS (ms)	QT (ms)	S_2 (ms)	S_3 (ms)
No therapy	76 ± 3	168 ± 5	93 ± 5	387 ± 7	249 ± 5	213 ± 11
Flecainide						
19 protected	73 ± 3	190 ± 7*	93 ± 3	386 ± 7	283 ± 5**	259 ± 5**
11 not protected	74 ± 4	187 ± 8	114 ± 9	415 ± 9*	275 ± 17	283 ± 24
Procainamide

ng/ml. All 4 of these patients clinically have signs of congestive heart failure (New York Heart Association class II), although their mean ejection fraction was 33%.

Adverse reactions: Few adverse reactions have been noted in the patients discharged with flecainide treatment using the lower dosage. One patient has complained of mild neurologic symptoms, primarily dizziness, vague paresthesias and nausea. Two patients had plasma flecainide levels of greater than 1,000 ng/ml before their daily dosage was reduced; both complained of feeling distinctly unwell, with confusion and dizziness. The flecainide levels were 1,081 and 1,099 ng/ml and the symptoms disappeared when the dosage was reduced. One patient had gastrointestinal discomfort with oral flecainide administration.

Serious sinus dysfunction with bradycardia developed in 4 patients predisposed to this problem by evidence of asymptomatic sick sinus syndrome. None of these patients had had significant sinus pauses while receiving previous antiarrhythmic therapy (2 patients receiving procainamide and 2 receiving quinidine) and none had required temporary or permanent pacing. When given flecainide, all 4 required placement of a permanent pacemaker for prolonged sinus pauses (from 2.0 to 3.7 seconds) with nodal or ventricular escape beats developing within 3 days after being started on a dose of flecainide, 100 mg twice daily. After continued observation over the next few days, pauses of longer than 3.5 seconds or paroxysmal atrial tachycardia with 7:1 block and a ventricular response of 31 were noted and a permanent pacemaker was needed in each case. Two other patients had chronic atrial fibrillation but no evidence of "tachy-brady" syndrome; neither of these patients required pacing. None of the other 15 patients with clinically normal sinus node function have demonstrated any instances of sinus or atrioventricular block.

Discussion

Flecainide has been reported to cause a marked reduction in VPC frequency.[3–8] This suppression in VPC frequency is also noted with other class IC drugs such as encainide.[16] These data suggest that flecainide may be a useful new agent for the treatment of VPCs. Less information is known regarding the efficacy of flecainide in patients with life-threatening arrhythmias and in patients undergoing electrophysiologic studies.[10,11]

We studied the effects of flecainide treatment in 40 patients with serious ventricular arrhythmias, all of whom had VT provoked at electrophysiologic testing without antiarrhythmic medication. With an ejection fraction of 45 ± 3% and having only failed 1.9 ± 0.2 drugs before referral, this group of patients would not be considered "drug-resistant," and therefore may be more representative of the usual patient who receives antiarrhythmic therapy for life-threatening arrhythmias. In this group, flecainide protected 65% of the patients. To allow comparison to other centers with a different referral population, we report data on the 30 patients tested with both procainamide and flecainide. Flecainide was as effective as procainamide treatment, 63% vs 60%. In populations with lower ejection fractions or who have failed treatment with more antiarrhythmic drugs, the absolute numbers will be lower, but we believe that flecainide is an effective agent that should be tested.

The correlation between success at acute testing and protection from clinical events in long-term follow-up appears good. In 11 months, 2 patients (11%) had an arrhythmia breakthrough during flecainide therapy, which resulted in 1 (5%) sudden death. This is consistent with results from other PES studies[11] and is consistent with the high risk of this population, which included 7 patients with previous cardiac arrest and 11 with hemodynamically significant, sustained VT. Without a concurrent control group, these numbers are difficult to interpret, but appear to be an improvement over mortality observed with historic controls, especially because none of the patients who had had a cardiac arrest before therapy have died.[17–20]

Flecainide appears to be a well tolerated drug, especially at the reduced doses used in this study. We had only 3 instances of central nervous system and gastrointestinal toxicity in our patients; all of these side effects have been noted by other investigators.[21,22] Four patients had a history of intermittent episodes of atrial fibrillation, flutter or supraventricular tachyarrhythmias and pauses suggestive of sick sinus syndrome. None of these patients had had sinus pauses during previous, ineffective antiarrhythmic therapy (procainamide in 2 patients and quinidine in 2) and none had required temporary or permanent pacing. When given flecainide, all 4 required placement of a permanent pacemaker for prolonged sinus pauses, which occurred within 3 days of oral therapy. Hellestrand et al[23] described sinus node function in 10 patients tested with flecainide during electrophysiologic studies. Although there were no statistically significant increases in the sinus node recovery times in either the patients with normal or abnormal sinus node function, 1 patient had a marked prolongation of her corrected sinus node recovery time, from 3,885 to 18,195 ms. They concluded that flecainide should be used with caution in patients with abnormal sinus node function. Vik-Mo, Ohm and Lund-Johansen[24] studied 11 patients with sinus node dysfunction and found a significant increase in the corrected sinus node recovery time, from 875 ± 181 to 1,727 ± 507 ms ($p < 0.05$). They also advised caution in using flecainide therapy in patients with sick sinus syndrome. Pacemaker thresholds appear to increase by as much as 200% with chronic oral flecainide therapy.[23] This may further increase the risk of patients with a sick sinus who are treated and later require a permanent pacemaker. These considerations should not decrease the utilization of this highly effective agent, but rather caution the prescriber to be observant for the patient who may require pacemaker implantation with flecainide therapy.

Dosage considerations are also important. Toxicity is increased when the level is increased over 1,000 ng/ml. Four patients required a reduction in their maintenance therapy or their plasma level would have gone into the toxic range. Besides the central nervous system and

gastrointestinal symptoms that could be avoided, levels over 1,000 ng may be more likely associated with arrhythmias. Because of a previous report of a case of flecainide toxicity that led to death,[12] we were cautious not to obtain high plasma levels and an associated increase in QRS duration. Flecainide in excessive concentrations may cause a wide complex tachycardia, leading to ventricular fibrillation or asystole unresponsive to defibrillation and pacing.[12] The known elevation in pacing threshold[23] and the probable increase in defibrillation threshold emphasizes the need for moderate plasma levels. Frequent early blood level monitoring during the first month and every 3 months thereafter can be of great help in this regard. Furthermore, evidence from the present study suggests that a subpopulation of patients with clinical symptoms of congestive heart failure may show a rise in flecainide plasma concentrations over time; these patients require more careful monitoring.[25]

Mechanism of action: The current study suggests that flecainide is effective in patients in whom it causes a significant prolongation in myocardial refractoriness as measured by the extrastimulus technique. Although intravenous flecainide therapy causes prolongation in the effective refractory period of the first extrastimulus in all patients tested (12 ± 3%), the change is not directly related to dose. In fact, patients protected by flecainide treatment had a 17 ± 2% increase in the first extrastimulus refractory period with a dose of 1.35 ± 0.1 mg/kg, whereas the nonprotected patients only had a 7 ± 3% increase, but received a higher mean dose of 1.9 ± 0.1 mg/kg. Of all the drugs studied in our laboratory, flecainide most clearly shows this differential prolongation in refractoriness between the patients in whom it was effective and ineffective. However, excessive prolongation of refractoriness could also be arrhythmogenic, as noted both in a previous report of a toxicity in a patient[12] as well as possibly explaining the flecainide toxicity in patients studied by Reid et al.[14]

Effect of Electrical Activation Site on Left Ventricular Performance in Ventricular Tachycardia Patients with Coronary Heart Disease

JOEL S. RAICHLEN, MD, JONATHAN M. LINKS, PhD, and PHILIP R. REID, MD

Some patients with ventricular tachycardia (VT) remain virtually asymptomatic, whereas others have syncope despite similar VT rates. The role of ventricular activation site on left ventricular (LV) function was examined in 10 patients undergoing electrophysiologic evaluation for recurrent ventricular arrhythmias. Radionuclide ventriculograms were acquired to calculate LV volumes and aortic or LV pressure was measured during right atrial and right ventricular (RV) pacing. RV apical pacing resulted in end-diastolic volumes similar to those achieved with right atrial pacing (171 ± 27 vs 175 ± 19 ml), whereas RV outflow tract pacing showed a trend toward lower volumes (168 ± 32 vs 177 ± 33 ml). Comparison between RV apical and RV outflow tract pacing showed that apical activation resulted in higher end-diastolic volumes (216 ± 26 vs 194 ± 22 ml, p = 0.020), end-systolic volumes (175 ± 25 vs 158 ± 20 ml, p = 0.041), stroke volumes (42 ± 4 vs 36 ± 6 ml, p = 0.046), peak rates of LV ejection (309 ± 57 vs 245 ± 40 ml/s, p = 0.034) and peak rates normalized for differences in end-diastolic volume (1.5 ± 0.3 vs 1.3 ± 0.3; p = 0.047) without a significant increase in peak pressures (131 ± 12 vs 127 ± 14 mm Hg, p >0.30) or ejection fractions (24 ± 5 vs 22 ± 4%, p = 0.187). These changes were accompanied by an increase in LV/RV stroke count ratios during RV apical vs RV outflow tract pacing (1.6 ± 0.2 vs 1.2 ± 0.2, p = 0.030), suggesting the development of mitral regurgitation. Temporal Fourier analysis of the radionuclide ventriculograms showed considerable variation in the LV patterns of emptying from different activation sites. It is hypothesized that the altered activation sequence associated with RV apical pacing disrupts papillary muscle function, inducing mitral regurgitation and, as a consequence, results in higher LV volumes and ejection rates than RV outflow tract activation. These site-dependent differences in LV performance suggest that the location of ventricular activation may be an important determinant of the hemodynamic consequences of sustained ventricular tachyarrhythmias.

(Am J Cardiol 1985;55:84–88)

Although ventricular tachycardia (VT) is often associated with severe hypotension, individual patients may present with a broad spectrum of hemodynamic responses to their tachyarrhythmias despite similar VT rates. The mechanisms accounting for the wide range of clinical effects is unknown. Considerable interest has been focused on localizing the specific site of initial activation in VT, but little attention has been directed to the hemodynamic consequences of the altered contraction pattern that results. Investigations of persons with normal hearts or those with valvular or a combination of cardiac diseases have shown no pacing site–dependent differences in left ventricular (LV) hemodynamics,[1–3] while another that focused on patients with coronary disease showed significant variation in cardiac index.[4] Since coronary artery disease is the most common underlying abnormality in patients with sustained ventricular arrhythmias, the origin of ectopic foci may play an important role in the consequences of the rhythm disturbances. Accordingly, we undertook this study to examine patients with coronary disease and recurrent ventricular arrhythmias in order to evaluate the influence of the site of electrical activation on LV function.

Methods

Study population: The subjects in this study consisted of 10 men with coronary heart disease undergoing electrophysiologic evaluation for recurrent ventricular tachycardia.

Their average age was 64 ± 3 years (mean ± standard error of the mean). None had clinical evidence of valvular regurgitation.

The protocol was approved by the institution's human investigations committee, and the subjects gave informed consent. The subjects fasted overnight in preparation for their catheterization study. No sedatives or routine medications were administered before the study.

Radionuclide ventriculograms: Red blood cells were labeled in vivo with 20 to 25 mCi of technetium-99m. Electrocardiogram-gated blood pool scans were then acquired during normal sinus rhythm using a mobile scintillation camera interfaced to a dedicated portable computer. The heart was imaged during normal sinus rhythm in the anterior and 40° left anterior oblique projections for 6-minute periods. During pacing, 3-minute images were acquired in the 40° left anterior oblique projection. Technically adequate images were obtained in all but 1 subject.

Pacing protocol: Pacing electrodes were positioned in the right atrium and a right ventricular (RV) site through the femoral vein. Before beginning the clinical electrophysiologic study, the hearts were paced from the right atrium and then simultaneously from the right atrial (RA) and the RV site at a rate of 100 beats/min. Simultaneous atrial and ventricular pacing was used to permit control of the atrium, thus preventing sinus competition and retrograde ventriculoatrial conduction while eliminating the atrial contribution to the end-diastolic volume.

Each sequence began with 1 minute of pacing to allow hemodynamic variables to reach a steady state. Pacing was then continued for an additional 3 minutes, during which arterial or LV pressure was recorded and gated blood pool scans were acquired. The procedure was repeated at each RV site used in the electrophysiologic evaluation, the most common being the RV apex and the RV outflow tract (Table I).

Data analysis: LV time-activity curves from automatically generated regions of interest were used to assess LV volumes by a reliable method which generates highly reproducible volumes.[5–8] End-diastolic volume, end-systolic volume, stroke volume and ejection fraction were determined from the volumes generated using the 16 images making up each cardiac cycle. The time course of the LV volume curve was used to determine the peak rate of LV ejection and the peak rate normalized for end-diastolic volume. Additional regions of interest were manually generated over the right and left ventricles to examine the ratio of LV vs RV stroke counts.[9] Temporal Fourier analysis was performed to visualize the pattern of ventricular emptying.[10] The peak arterial or LV pressure was determined from the equilibrium portion of each pacing sequence. The results found during isorhythmic pacing sequences were compared using analysis of variance for multiple group comparisons and the two-tailed *t* test for assessment of paired data.

Results

The characteristics of the study population are shown in Table I. The gated blood pool scans obtained at rest during normal sinus rhythm showed an average ejection fraction of 35 ± 4% and average end-diastolic volume of 203 ± 23 ml. None had LV/RV stroke count ratios below 1.0, indicating the absence of tricuspid regurgitation at rest.

Similar end-diastolic volumes were found during RA pacing and simultaneous pacing from the right atrium and the RV apex (175 ± 19 vs 171 ± 27 ml), whereas pacing from the right atrium and the RV outflow tract showed a trend toward lower volumes (177 ± 33 vs 168 ± 32 ml) (Fig. 1) (differences not statistically significant). Comparison between pacing from the RV apex vs the RV outflow tract showed higher end-diastolic volumes during RV apical activation (216 ± 26 vs 194 ± 22 ml, p = 0.020) (Fig. 2). RV apical pacing also resulted in higher end-systolic volumes than RV outflow tract pacing (175 ± 25 vs 158 ± 20 ml; p = 0.041). All but 1 patient had a higher ejection fraction during RV apical pacing, though the differences were not statistically significant (24 ± 5 vs 22 ± 4%; p = 0.187). With higher end-diastolic volumes and a trend toward higher ejection fractions, RV apical pacing resulted in higher stroke volumes than pacing from the RV outflow tract (42 ± 4 vs 36 ± 6 ml, p = 0.046). The peak rate of LV ejection was also higher during RV apical pacing (309 ± 57 vs 245 ± 40 ml/s, p = 0.034), as was the peak ejection rate normalized for differences in end-diastolic volume (1.5 ± 0.3 vs 1.3 ± 0.3 end-diastolic volumes/s, p = 0.047) (Fig. 3). Despite the higher ejection rates and larger volumes, there were no differences in the peak pressures generated during RV apical vs RV outflow tract pacing (131 ± 12 vs 127 ± 14 mm Hg; p > 0.30). There were differences, however, in the LV/RV stroke count ratios, with higher values found during RV apical than RV outflow tract pacing (1.6 ± 0.2 vs 1.2 ± 0.2, p = 0.030).

The Fourier phase sequences resulting from the activation sites suggested very different patterns of ventricular emptying. Figure 4, top panel, shows the su-

praventricular activation sequence in which the mid- to high septum is the initial site of LV emptying in the left anterior oblique projection. Once begun, the remainder of the ventricle empties in rapid succession. Figure 4, middle panel, shows the pattern resulting from RV apical stimulation in the same patient. In this case the inferior apex is the first region of the left ventricle to empty, with the sequence gradually progressing from apex to base. The emptying pattern proceeded at a similar rate during RV outflow tract pacing (Fig. 4, bottom). However, in contrast to RV apical activation, the LV emptying sequence during RV outflow tract stimulation proceeded from base to apex.

Discussion

The importance of the site of ectopic ventricular activation on myocardial function has rarely been demonstrated in man. The 1 study that did so showed higher cardiac indexes during epicardial pacing from the RV apex than the RV outflow tract or the LV apex in open-chest, anesthetized patients undergoing coronary surgery.[4] The current study of endocardial pacing in conscious, unmedicated patients showed consistent results, i.e., that the stroke volumes and peak rates of ejection were higher when activation was initiated from the RV apex than from the RV outflow tract. A higher peak ejection rate normalized for differences in end-diastolic volume suggests better ventricular function,[11,12] whereas a higher stroke volume indicates higher cardiac output. The cause of such site-dependent differences in function has not been previously examined in man.

Simultaneous RA and RV stimulation eliminated the augmentation of LV filling normally provided by atrial contraction. This would be expected to reduce end-diastolic volume relative to RA pacing, particularly in a population with myocardial dysfunction due to ischemic heart disease.[13,14] The comparison between RA and RV apical pacing showed no differences in end-diastolic volume, while RV outflow tract activation showed the expected trend toward reduced volumes. Since there was no significant change in ejection fraction between sites, this increase in end-diastolic volume during RV apical pacing would be expected to result in a higher stroke volume and, as a consequence, a higher rate of ejection as was observed. Although preload conditions may contribute to the increase in ejection rate, normalizing for end-diastolic volume did not eliminate the site-dependent differences in peak rates of ejection.

Despite the higher stroke volumes and peak rates of ejection associated with RV apical pacing, there was no increase in peak pressures. This would be reasonable if a portion of the stroke volume went retrograde across an incompetent mitral valve, reducing the volume of blood ejected into the systemic circulation. The induction of mitral incompetence could not only explain the increase in end-diastolic volume, but also, by providing a low pressure conduit for the regurgitation of blood, could account for the increase in peak rates of ejection and stroke volume. Such an underlying mechanism is supported by the LV/RV stroke count ratios,

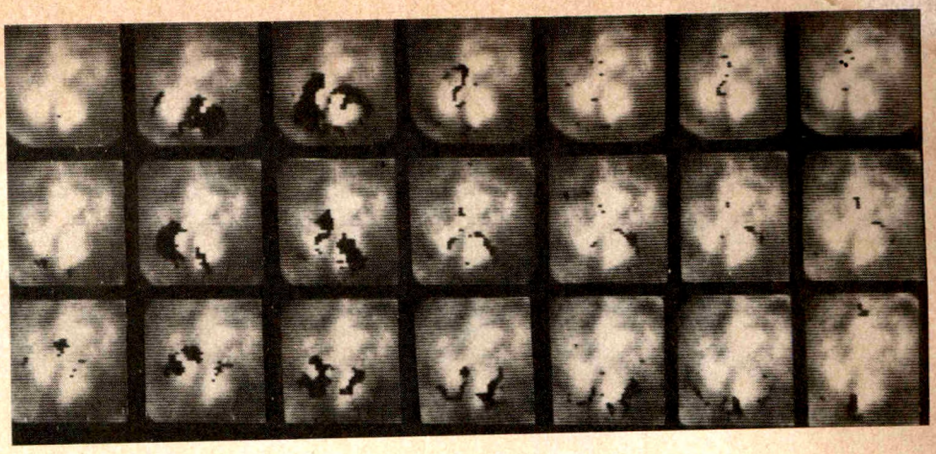

FIGURE 4. Patterns of ventricular emptying during systole displayed as the sequence of pixels (**black dots**) progressing over a composite 40° left anterior oblique gated blood pool image. The images on the left show the areas of the ventricles in which emptying first occurs. Each image in the sequence represents 1/16 of the cardiac cycle. **Top,** supraventricular activation; **middle,** right ventricular apical activation; **bottom,** right ventricular outflow tract activation.

which were significantly higher during RV apical than RV outflow tract pacing.

The likelihood of inducing mitral regurgitation during ventricular activation is enhanced by the loss of atrial contraction. Normally, atrial systole increases ventricular end-diastolic pressure so that the relaxation that follows results in a lower pressure in the atrium than the ventricle. This pressure gradient promotes closure of the atrioventricular valves before the onset of ventricular systole. In the absence of atrial contraction, atrial and ventricular pressures remain equal at end-diastole. With the onset of ventricular contraction, ventricular pressure rapidly rises and a large regurgitation of blood can occur as the atrioventricular valves swing shut from the open position.[15,16] Several studies in animals[15–17] and in man[18] in which atrial pressure tracings were examined have shown evidence of mitral regurgitation during ventricular pacing, whereas others have found no mitral regurgitation during ectopic ventricular activation.[19,20] The results of this study suggest these conflicting findings could relate to the specific locations at which initial ventricular activation occurred. This mechanism is supported by recent observations made during pacing in a canine model.[21]

The mechanism by which certain sites lead to the induction of mitral incompetence may involve the disruption of normal papillary muscle function. In the canine heart, papillary muscle lengthening and shortening has been shown to play an important role in promoting proper coaptation of the mitral valve at end-diastole, in maintaining normal atrioventricular valve function during isovolumic contraction, and in preventing prolapse of the valve leaflets during systolic ejection.[22,23] While the papillary muscles are activated early in systole during normal conduction, the normal contraction sequence can be considerably altered by ectopic electrical excitation.[24] The different contraction patterns suggested by the patterns of emptying during ectopic activation may cause varying delay in papillary muscle contraction relative to the rise of interventricular pressure. In this way, certain stimulation sites may prevent proper apposition of the mitral leaflets, thus precipitating mitral regurgitation. This mechanism may be particularly important in ischemic heart disease, wherein regional contraction abnormalities (particularly at high heart rates) would exacerbate papillary muscle dysfunction.

In this investigation, the study population was characterized by severe myocardial dysfunction and, in particular, by ischemic heart disease. The presence of these abnormalities may have been important in enabling the demonstration of statistically significant, site-dependent functional alterations, despite the small number of patients paced from multiple RV sites. Future investigations should consider the specific myocardial substrate abnormalities that are present when designing studies to evaluate the hemodynamic effects of ectopic activation.

LEDERLE LABORATORIES INTRODUCES

NEW *1 tab q.d.*

MAXZIDE™

Triamterene **75 mg**/Hydrochlorothiazide **50 mg**/Lederle

THE FIRST AND ONLY REPLACEMENT FOR THE LESS BIOAVAILABLE TRIAMTERENE/HYDROCHLOROTHIAZIDE FORMULATION... PROVEN SUPERIOR IN BIOAVAILABILITY

Please see last page of this advertisement for brief summary of prescribing information.

NEW *1 tab q.d.*

MAXZIDE™

Triamterene **75 mg**/Hydrochlorothiazide **50 mg**/Lederle

DELIVERS THE PRESCRIBED DOSE...

PROVIDES OPTIMAL ABSORPTION OF 75 MG TRIAMTERENE/ 50 MG HYDROCHLOROTHIAZIDE

A CLINICALLY SAFE AND EFFECTIVE ALTERNATIVE IN POTASSIUM-SPARING, ANTIHYPERTENSIVE THERAPY

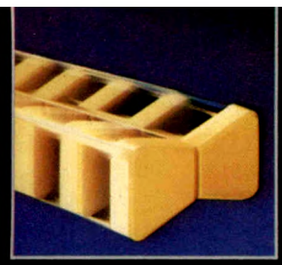
—FOR PATIENTS ON HYDROCHLOROTHIAZIDE WHO DEVELOP HYPOKALEMIA

—FOR NEWLY DIAGNOSED PATIENTS IN WHOM THE DEVELOPMENT OF HYPOKALEMIA CANNOT BE RISKED

—FOR PATIENTS TRANSFERRED FROM DYAZIDE®*

For the first time, a reliable alternative to the Dyazide formulation of triamterene/hydrochlorothiazide — new MAXZIDE. In a transfer safety study, patients taking up to four Dyazide capsules daily were effectively transferred to MAXZIDE q.d. with no compromise in clinical condition.[1]

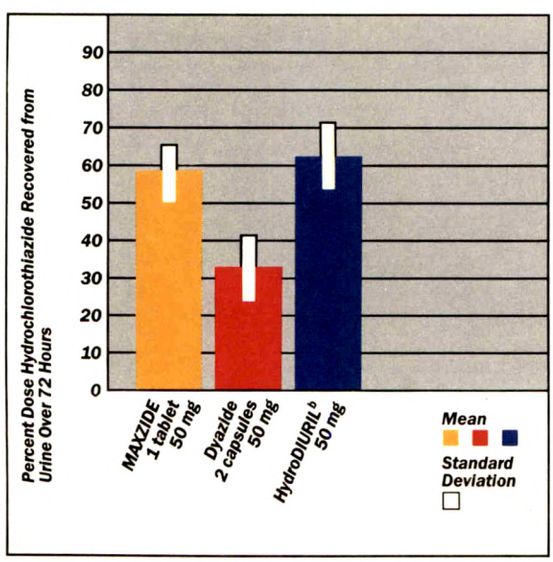
*Trademark of SK&F Co., Carolina, P.R.



SUPERIOR DRUG DELIVERY AND ABSORPTION — TABLET TO TABLET, PATIENT TO PATIENT

MAXZIDE is optimally bioavailable and consistently delivers the prescribed dose of 75 mg triamterene and 50 mg hydrochlorothiazide. Dyazide, on the other hand, exhibits poor bioavailability. When given in equivalent doses, Dyazide delivers approximately half the amount of hydrochlorothiazide as MAXZIDE. Similarly, two Dyazide capsules deliver less than half the amount of triamterene as one MAXZIDE tablet.[2]

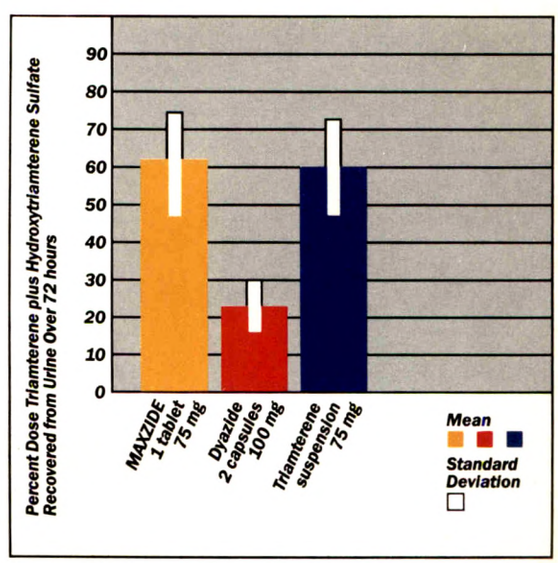
Percent dose of hydrochlorothiazide recovered from urine over 72 hours in subjects[a] given single oral doses



[a]Data from a study of 24 subjects.

[b]HydroDIURIL is the registered trademark of Merck & Co., Inc., for hydrochlorothiazide.

Percent dose of triamterene recovered from urine over 72 hours in subjects[a] given single oral doses



[a]Data from two studies of 24 subjects each.

Triamterene **75 mg**/Hydrochlorothiazide **50 mg**/Lederle

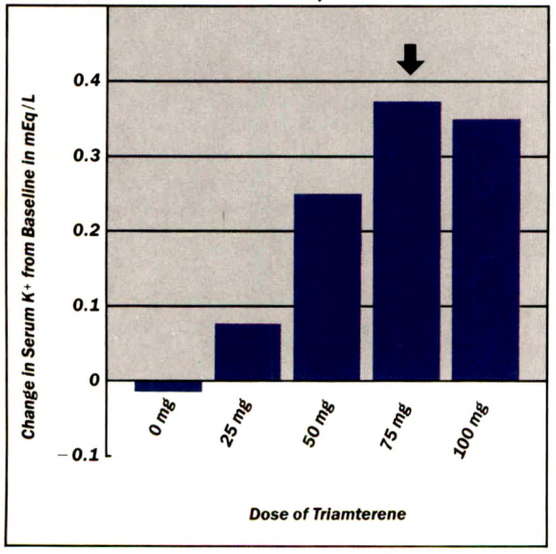
HYDROCHLOROTHIAZIDE EFFECTIVENESS WITH THE OPTIMAL DOSE OF TRIAMTERENE FOR POTASSIUM CONSERVATION

PROVEN FORMULATION MAXIMIZES POTASSIUM-SPARING EFFECT OF TRIAMTERENE

In a clinical dose-response evaluation, 75 mg triamterene daily most successfully corrected the hypokalemic effect of repeated daily doses of 50 mg hydrochlorothiazide.[3*]

Dose-response evaluation of triamterene's potassium-sparing activity in patients[a] rendered hypokalemic with long-term daily doses of 50 mg hydrochlorothiazide

*Ordinarily, triamterene does not entirely reverse the kaliuretic effect of hydrochlorothiazide.



[a]Data from a study of 49 patients.

CLINICALLY SAFE AND WELL TOLERATED

MAXZIDE can be prescribed with confidence for patients transferred from Dyazide to provide the administered dose of hydrochlorothiazide while maintaining clinically acceptable serum potassium levels. Patients previously receiving no diuretic medication and patients previously taking up to four Dyazide capsules daily have been successfully treated with MAXZIDE q.d. with no compromise in clinical condition.[1†]

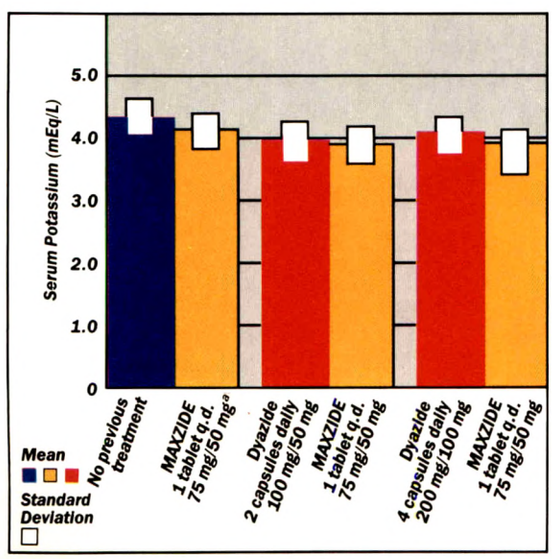
No clinically significant changes in serum potassium levels after 4 weeks of therapy with MAXZIDE one tablet q.d. in 138 patients previously untreated or transferred from Dyazide



[a]All dose ratios listed as triamterene in mg/hydrochlorothiazide in mg.

[†]Abnormal elevation of serum potassium levels (≥ 5.5 mEq/liter) can occur with all potassium-conserving diuretic combinations, including MAXZIDE. Hyperkalemia is more likely to occur in patients with renal impairment, diabetes (even without evidence of renal impairment), or in elderly or severely ill patients. Since uncorrected hyperkalemia may be fatal, serum potassium levels must be monitored at frequent intervals especially in patients first receiving MAXZIDE, when dosages are changed or with any illness that may influence renal function.

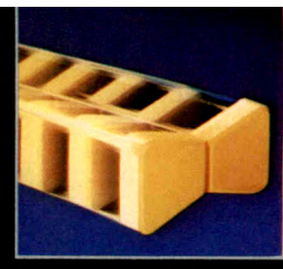
MAXZIDE™

Triamterene **75 mg**/Hydrochlorothiazide **50 mg**/Lederle



— FOR PATIENTS ON HYDROCHLOROTHIAZIDE WHO DEVELOP HYPOKALEMIA
— FOR NEWLY DIAGNOSED PATIENTS IN WHOM THE DEVELOPMENT OF HYPOKALEMIA CANNOT BE RISKED
— FOR PATIENTS TRANSFERRED FROM DYAZIDE

BRIEF SUMMARY
Please see package insert for full prescribing information.
INDICATIONS AND USAGE: *MAXZIDE is indicated for the treatment of hypertension or edema in patients who develop hypokalemia on hydrochlorothiazide alone. It is also indicated for those patients who require a thiazide diuretic and in whom the development of hypokalemia cannot be risked (e.g., patients on digitalis preparations or with a history of cardiac arrhythmias, etc.).* ***This fixed combination drug is not indicated for the initial therapy of edema or hypertension except in individuals in whom the development of hypokalemia cannot be risked.*** *MAXZIDE may be used alone or in combination with other antihypertensive drugs such as beta-blockers. Since MAXZIDE may enhance the actions of these drugs, dosage adjustments may be necessary. Usage in Pregnancy: The routine use of diuretics in an otherwise healthy woman is inappropriate and exposes mother and fetus to unnecessary hazards. Diuretics do not prevent development of toxemia in pregnancy, and there is no satisfactory evidence that they are useful in the treatment of developed toxemia.*
CONTRAINDICATIONS: *Hyperkalemia: MAXZIDE should not be used in the presence of elevated serum potassium levels (greater than 5.5 mEq/liter). If hyperkalemia develops, this drug should be discontinued and a thiazide alone should be substituted. Concomitant use with other potassium conserving agents such as spironolactone, amiloride HCl or other formulations containing triamterene. Concomitant potassium supplementation in the form of medication, potassium-containing salt substitute or potassium-enriched diets should also not be used. Contraindicated in patients with anuria, acute and chronic renal insufficiency or significant renal impairment. Hypersensitivity to either component separately or other sulfonamide-derived drugs.*
WARNINGS: *Hyperkalemia.*

> *Abnormal elevation of serum potassium levels (greater than or equal to 5.5 mEq/liter) can occur with all potassium conserving agents including MAXZIDE. Hyperkalemia is more likely to occur in patients with renal impairment, diabetes (even without evidence of renal impairment), or elderly or severely ill patients. Since uncorrected hyperkalemia may be fatal, serum potassium levels must be monitored at frequent intervals especially in patients first receiving MAXZIDE, when dosages are changed, or with any illness that may influence renal function.*

If hyperkalemia is suspected, (warning signs include paresthesias, muscular weakness, fatigue, flaccid paralysis of the extremities, bradycardia and shock) an electrocardiogram (ECG) should be obtained. Monitor serum potassium levels because mild hyperkalemia may not be associated with ECG changes. If hyperkalemia is present, MAXZIDE should be discontinued immediately and a thiazide alone should be substituted. If the serum potassium level exceeds 6.5 mEq/liter, more vigorous therapy is required. The clinical situation dictates the procedures to be employed. These include the intravenous administration of calcium chloride solution, sodium bicarbonate solution and/or the oral or parenteral administration of glucose with a rapid acting insulin preparation. Cationic exchange resins such as sodium polystyrene sulfonate may be orally or rectally administered. Persistent hyperkalemia may require dialysis. The development of hyperkalemia associated with potassium-sparing diuretics is accentuated in the presence of renal impairment (see CONTRAINDICATIONS). Patients with mild renal functional impairment should not receive this drug without frequent and continued monitoring of serum electrolytes. Cumulative drug effects may be observed in patients with impaired renal function. The renal clearances of hydrochlorothiazide, the pharmacologically active metabolite of triamterene, and the sulfate ester of hydroxytriamterene have been shown to be reduced and the plasma levels increased following MAXZIDE administration to elderly patients and patients with impaired renal function. Hyperkalemia has been reported in diabetic patients with the use of potassium conserving agents even in the absence of apparent renal impairment. Avoid MAXZIDE in diabetic patients. If it is employed, serum electrolytes must be frequently monitored. Metabolic or Respiratory Acidosis: Potassium conserving therapy should also be avoided in severely ill patients in whom respiratory or metabolic acidosis may occur, since acidosis may be associated with rapid elevations in serum potassium levels. If MAXZIDE™ triamterene 75mg/hydrochlorothiazide 50mg is employed, frequent evaluations of acid/base balance and serum electrolytes are necessary.
PRECAUTIONS: *Electrolyte Imbalance and BUN Increases: Patients receiving MAXZIDE should be carefully monitored for fluid or electrolyte imbalances, i.e., hyponatremia, hypochloremic alkalosis, hypokalemia and hypomagnesemia. Serum and urine electrolyte determinations should be frequently performed and are especially important when the patient is vomiting or receiving parenteral fluids. Warning signs or symptoms of fluid and electrolyte imbalance include: dryness of mouth, thirst, weakness, lethargy, drowsiness, restlessness, muscle pains or cramps, muscular fatigue, hypotension, oliguria, tachycardia and gastrointestinal disturbances such as nausea and vomiting.*

Any chloride deficit during thiazide therapy is generally mild and usually does not require any specific treatment except under extraordinary circumstances (as in liver disease or renal disease). Dilutional hyponatremia may occur in edematous patients in hot weather; appropriate therapy is water restriction, rather than administration of salt, except in rare instances when the hyponatremia is life threatening. In actual salt depletion, appropriate replacement is the therapy of choice.

Hypokalemia may develop with thiazide therapy, especially with brisk diuresis, when severe cirrhosis is present, or during concomitant use of corticosteroids, ACTH, amphotericin B or after prolonged thiazide therapy. However, hypokalemia of this type is usually prevented by the triamterene component of MAXZIDE.

Interference with adequate oral electrolyte intake will also contribute to hypokalemia. Hypokalemia can sensitize or exaggerate the response of the heart to the toxic effects of digitalis (e.g., increased ventricular irritability).

MAXZIDE may produce an elevated blood urea nitrogen level (BUN), creatinine level or both. This is probably not the result of renal toxicity but is secondary to a reversible reduction of the glomerular filtration rate or a depletion of the intravascular fluid volume. Periodic BUN and creatinine determinations should be made especially in elderly patients, patients with suspected or confirmed hepatic disease or renal insufficiencies. If azotemia increases, MAXZIDE should be discontinued.

Hepatic Coma: MAXZIDE should be used with caution in patients with impaired hepatic function or progressive liver disease, since minor alterations of fluid and electrolyte balance may precipitate hepatic coma. Renal Stones: Triamterene has been reported in renal stones in association with other calculus components. MAXZIDE should be used with caution in patients with histories of renal lithiasis. Folic Acid Deficiency: Triamterene is a weak folic acid antagonist and may contribute to the appearance of megaloblastosis in instances where folic acid stores are decreased. In such patients, periodic blood evaluations are recommended. Hyperuricemia: Hyperuricemia may occur or acute gout may be precipitated in certain patients receiving thiazide therapy. Metabolic and Endocrine Effects: The thiazides may decrease serum PBI levels without signs of thyroid disturbance.

Calcium excretion is decreased by thiazides. Pathological changes in the parathyroid gland with hypercalcemia and hypophosphatemia have been observed in a few patients on prolonged thiazide therapy. The common complications of hyperparathyroidism such as renal lithiasis, bone resorption, and peptic ulceration have not been seen. Thiazides should be discontinued before carrying out tests for parathyroid function.

Insulin requirements in diabetic patients may be increased, decreased or unchanged. Latent diabetes mellitus may become manifest during thiazide administration. Hypersensitivity: Sensitivity reactions to thiazides may occur in patients with or without a history of allergy or bronchial asthma.

Possible exacerbation or activation of systemic lupus erythematosus by thiazides has been reported. Drug Interactions: Thiazides may add to or potentiate the action of other antihypertensive drugs.

The thiazides may decrease arterial responsiveness to norepinephrine. This diminution is not sufficient to preclude effectiveness of the pressor agent for therapeutic use. Thiazides have also been shown to increase responsiveness to tubocurarine.

Lithium, when given with diuretics, reduces renal clearance and increases the risk of lithium toxicity. Refer to the package insert on lithium before use of such concomitant therapy.

Acute renal failure has been reported in a few patients receiving indomethacin and other formulations containing triamterene and hydrochlorothiazide. Caution is therefore advised when administering nonsteroidal anti-inflammatory agents with MAXZIDE.

Drug/Laboratory Test Interactions: Triamterene and quinidine have similar fluorescence spectra; thus MAXZIDE may interfere with the measurement of quinidine.

Pregnancy: Category C: The safe use of MAXZIDE in pregnancy has not been established. Animal reproduction studies have not been conducted with MAXZIDE™ triamterene 75mg/hydrochlorothiazide 50mg. It is also not known if MAXZIDE can cause fetal harm when administered to a pregnant woman or can affect reproductive capacity. Thiazides cross the placental barrier and appear in cord blood. The use of thiazides in pregnant women requires that the anticipated benefit be weighed against possible hazards to the fetus. These hazards include fetal or neonatal jaundice, thrombocytopenia, pancreatitis, and possibly other adverse reactions which have occurred in the adult. MAXZIDE should be given to a pregnant woman only if clearly needed.

Nursing Mothers: Thiazides appear in breast milk. If the use of MAXZIDE is deemed essential, the patient should stop nursing. Pediatric Use: The safety and effectiveness of MAXZIDE in children has not been established.
ADVERSE REACTIONS: *Side effects observed in association with the use of MAXZIDE include drowsiness and fatigue, insomnia, muscle cramps and weakness, headache, nausea, appetite disturbance, vomiting, diarrhea, constipation, dizziness, decreased sexual performance, shortness of breath and chest pain, dry mouth, depression and anxiety. These adverse reactions are common to other triamterene and hydrochlorothiazide containing products. Other adverse reactions include:*
Hydrochlorothiazide:
Gastrointestinal: anorexia, gastric irritation, cramping, jaundice (intrahepatic cholestatic jaundice), pancreatitis, sialadenitis. Central Nervous System: vertigo, paresthesias, xanthopsia. Hematologic: leukopenia, agranulocytosis, thrombocytopenia, aplastic anemia, hemolytic anemia, megaloblastosis. Cardiovascular: orthostatic hypotension (may be aggravated by alcohol, barbiturates, or narcotics). Hypersensitivity: anaphylaxis, purpura, photosensitivity, rash, urticaria, necrotizing angiitis (vasculitis, cutaneous vasculitis), fever, respiratory distress including pneumonitis. Other: hyperglycemia, glycosuria, hyperuricemia, restlessness, transient blurred vision.
Triamterene:
Hypersensitivity: anaphylaxis, photosensitivity and rash. Other: Triamterene has been reported in renal stones in association with other calculus materials. Triamterene has been associated with blood dyscrasias. Whenever adverse reactions are moderate to severe, therapy should be reduced or withdrawn.
DOSAGE AND ADMINISTRATION: *The recommended dosage of MAXZIDE is one tablet daily with appropriate monitoring of serum potassium levels (see WARNINGS). Patients receiving 50 mg of hydrochlorothiazide who become hypokalemic may be transferred to MAXZIDE directly. In patients requiring 50 mg of hydrochlorothiazide in whom hypokalemia cannot be risked, therapy may be initiated with MAXZIDE. There is no clinical experience with doses exceeding one tablet daily.*

Clinical studies have shown that patients already taking less bioavailable formulations of triamterene and hydrochlorothiazide (totaling 50-100 mg of hydrochlorothiazide and 100-200 mg of triamterene) may be safely changed to one MAXZIDE™ triamterene 75mg/hydrochlorothiazide 50mg tablet per day; these patients should be monitored clinically and with serum potassium after the transfer.

Intravenous and Oral Loading Versus Oral Loading Alone with Amiodarone for Chronic Refractory Ventricular Arrhythmias

NICHOLAS Z. KERIN, MD, ROGER D. BLEVINS, PharmD, HOWARD FRUMIN, MD, KATHY FAITEL, RN, BSN, and MELVYN RUBENFIRE, MD

To determine whether combined intravenous (i.v.) and oral loading with amiodarone can shorten its onset of action, a comparative study was conducted. Twenty patients with refractory ventricular arrhythmias were treated with amiodarone. All patients had frequent (≥30/hour) and complex (repetitive) ventricular premature beats on a 48-hour baseline Holter recording. Ten patients (group A) received oral loading alone: 800 mg/day for 7 days, 600 mg/day for 3 days, then a maintenance dose 200 to 400 mg/day. Ten patients (group B) received i.v. and oral loading: 5 mg/kg i.v., and then the same regimen as for group A. Follow-up 24-hour Holter recordings were obtained daily for 7 days, weekly for 1 month, and then monthly. Arrhythmia control was defined as at least a 70% reduction in ventricular premature beats, a 90% or greater reduction in couplets and abolition of ventricular tachycardia. The time to optimal ventricular arrhythmia control was shorter for group B (20 ± 18 vs 105 ± 83 days, $p < 0.05$) and the cumulative amiodarone dose at the time of control was smaller for group B (10 ± 8 vs 48 ± 39 g, $p < 0.05$). No complications were encountered with i.v. amiodarone. Thus, initial loading with i.v. amiodarone can shorten the time to optimal ventricular arrhythmia control and lower the cumulative dose required.

(Am J Cardiol 1985;55:89–91)

Amiodarone is a unique antiarrhythmic agent that is effective in the treatment of both atrial and ventricular arrhythmias.[1–3] Early experience with amiodarone has revealed a significant delay in its onset of antiarrhythmic activity, perhaps because of its long half-life.[4] Several investigators have successfully reduced the lag-time by administering large oral loading doses. Nevertheless, in patients with potentially life-threatening arrhythmias, the delay experienced with oral loading regimens is often unacceptable. We compared a combined intravenous (i.v.) and oral loading regimen of amiodarone to an oral loading alone and evaluated the time and cumulative dose required for optimal ventricular arrhythmia control for each approach.

Methods

Patients: The study population included 20 consecutive patients referred to the Arrhythmia Research Clinic at Sinai Hospital of Detroit for management with amiodarone. All patients had a history of chronic ventricular arrhythmias and were intolerant of or refractory to therapeutic doses of conventional antiarrhythmic agents, including quinidine, procainamide, disopyramide and propranolol. In several patients treatment had failed with investigational antiarrhythmic drugs, including aprindine, tocainide, lorcainide and mexiletine. Patients with more than first-degree atrioventricular block without permanent pacing and those with familial long QT syndromes were excluded from this study.

Baseline studies: Antiarrhythmic medications were discontinued for a period of at least 5 half-lives. Digitalis, β-blocking drugs, calcium antagonist drugs and nitrates were permitted when clinically indicated. After washout, a standard 12-lead electrocardiogram (ECG) and a 24- to 48-hour continuous ECG (Holter) were recorded. Holter recordings were stored on magnetic tapes and computer-scanned for the frequency of ventricular premature beats (VPBs), coupled VPBs and ventricular tachycardia (VT), defined as 3 or more consecutive VPBs. Each patient underwent ophthalmologic examinations, routine laboratory studies (including T3, T4 and reverse T3) and chest x-ray.

Study design: The first 10 consecutive patients (group A) received oral amiodarone loading alone. The oral loading regimen consisted of 800 mg/day for 7 days, then 600 mg/day for 3 days, followed by a maintenance dose of 200 to 400 mg/day, depending on clinical judgment. The next 10 patients

Manuscript received June 14, 1984, revised manuscript received September 7, 1984, accepted September 10, 1984.
Address for reprints: Roger D. Blevins, PharmD, Department of Medicine, Sinai Hospital of Detroit, 6767 West Outer Drive, Detroit, Michigan 48235.

(group B) received a combination of i.v. and oral amiodarone loading. This regimen consisted of 5 mg/kg infused over 30 minutes, followed by the group A oral loading regimen. During the infusion, the ECG was monitored continuously by telemetry, and heart rate and blood pressure were determined every 10 minutes. For both groups, 24-hour Holter ECGs were recorded daily for 7 days, then weekly for 1 month, and monthly thereafter. Arrhythmia control was defined as at least a 70% reduction in total VPBs and at least a 90% reduction in coupled VPBs and complete abolition of VT.

Statistical analysis: Between-group differences with respect to baseline and treatment characteristics were analyzed using the unpaired *t* test and significance was inferred at the $p < 0.05$ level.

Results

Patient characteristics: Twenty patients with chronic refractory ventricular arrhythmias were treated with amiodarone. Ten patients (group A) received an oral loading regimen and 10 patients (group B) received a combined i.v. and oral loading regimen. There were no statistically significant differences between group A and group B with respect to age (65 vs 59 years), sex (70% vs 50% male), baseline ventricular arrhythmias (292 vs 265 VPBs/hour, 35 vs 11 couplets/hour and 4 vs 11 VT/24 hours), or number of previous antiarrhythmic drug trials (3.5 vs 3.2 conventional and 1.1 vs 0.2 investigational drug trials per patient).

Control of ventricular arrhythmias: In 7 patients in group A (70%) and in all 10 patients in group B (100%), the ventricular arrhythmias were eventually controlled. The difference was not statistically significant.

The time to arrhythmia control was shorter and the cumulative amiodarone dose at the time of control was smaller for group B than for group A. In group B arrhythmias were controlled 20 ± 18 days (mean ± standard deviation) into therapy with a cumulative amiodarone dose of 10 ± 8 g. In group A arrhythmias were controlled 105 ± 83 days into therapy with a cumulative dose of 48 ± 39 g. Between-group differences in time to control and cumulative dose were significant ($p < 0.05$ and $p < 0.05$, respectively).

Amiodarone was safely initiated and well tolerated in all patients. No patient experienced untoward effects that required discontinuation of treatment during intravenous loading, oral loading or maintenance therapy.

Discussion

Previous studies: The clinical value of amiodarone has been hampered by its delayed onset of antiarrhythmic activity. Several investigators have reported that various oral loading regimens can shorten the lag-time. Rakita and Sobel,[5] in a comparative study with oral amiodarone, reported that the time to complete arrhythmia control was 31 ± 10 days for patients given 200 mg/day and 16 ± 11 days for patients given 1,400 mg/day. Holter ECGs were recorded weekly and arrhythmia control was defined as abolition of recurrent VT and reduction of total VPBs to fewer than 6 per minute.

Other investigators have reported the onset of antiarrhythmic action as 2 to 28 days in uncontrolled studies using various oral loading regimens.[1,6–8] However, some of these studies included patients with supraventricular arrhythmias, and definitions of arrhythmia control varied.

Mostow et al[9] reported control of complex ventricular arrhythmias within 48 hours in 7 patients treated with amiodarone infusions (total dose 1,948 to 4,637 mg) which maintained serum concentrations of 2.0 to 2.5 μg/ml. A more recent study by the same group,[10] using i.v. amiodarone loading (5 mg/kg) followed by a 2-step maintenance infusion guided by pharmacokinetic data (average 2.3 mg/min for 12 hours, then 0.7 mg/min for 36 hours), demonstrated complete suppression of VT in 3 of 7 patients, with a mean VPB suppression of 60%, couplet suppression of 74% and VT suppression of 85%. They concluded that i.v. amiodarone is rapidly effective in control of life-threatening ventricular arrhythmias.

Nademanee et al[11] studied the electrophysiologic effects of amiodarone in 20 patients. Single bolus injections (5 mg/kg) had no significant electrophysiologic effects and the time to significant VPB suppression was not different between 4 patients given 1,600 mg/day orally and 4 patients given a continuous infusion of 50 mg/hour. They concluded that i.v. amiodarone did not shorten the onset of action.

Study design: Combined i.v. and oral loading with amiodarone has not been studied in comparative fashion. In the present comparative study, a relatively low-dose loading and maintenance regimen was chosen in an effort to avoid dose-related side effects (e.g., pulmonary fibrosis), an approach recently advocated by the European Collaborative Group.[12] This low-dose approach, as well as more stringent criteria for optimal control and longer intervals between follow-up visits, make between-study comparisons difficult, but may explain the longer lag-times observed in this study compared to previous studies.

Although the study design was nonrandomized, clinical characteristics were not significantly different between groups. Some of the variability in lag-time observed between groups may be the result of a slightly larger total loading dose for group B or differences in mean pharmacokinetic properties. However, it is unlikely that either of these could fully explain the 5-fold differences observed.

Speculations on the mechanism of intravenous amiodarone: Although significant antiarrhythmic effects have been observed within 24 hours of i.v. amiodarone administration, our data suggest that considerably more time is required for optimal suppression of both frequency and complexity of ventricular arrhythmias. This would indicate that some slow, indirect mechanism, such as accumulation of active metabolite or hormonal effect, is at least partially responsible for its full antiarrhythmic effect. Perhaps the i.v. preparation, having higher systemic availability and more rapid tissue distribution results in a more rapid attainment of indirect effects.

Despite a small patient population and nonrandomized design, we conclude that combined i.v. and oral

loading with amiodarone is well tolerated, shortens the time to optimal arrhythmia control, and reduces the cumulative dose required to achieve arrhythmia control.

Intravenous Quinidine: Relations Among Concentration, Tachyarrhythmia Suppression and Electrophysiologic Actions with Inducible Sustained Ventricular Tachycardia

HENRY J. DUFF, MD, D. GEORGE WYSE, MD, PhD, DANTE MANYARI, MD, and L. BRENT MITCHELL, MD

A computer simulation was used to devise quinidine sulfate infusions to produce pseudo-steady-state concentrations in the low (8 μM/liter) and high (14 μM/liter) therapeutic ranges, avoiding high peak concentrations. Using this infusion, efficacy and electrophysiologic actions of quinidine sulfate were assessed in 21 patients with sustained inducible ventricular tachycardia (VT) when concentrations were 12.6 ± 11 μM/liter (mean ± standard deviation) and 18 ± 9 μM/liter. Although mean concentrations approximated target levels, there was substantial individual variation. A reciprocal linear relation ($r = 0.8$, $p < 0.01$) was noted between resultant serum concentrations and drug-free ejection fraction (EF). Transient hypotension occurred early in 3 patients, 2 of whom had a normal left ventricular (LV) EF. No hemodynamic compromise was seen in patients with LVEFs of less than 30%. Induced VT was suppressed in 5 patients at low concentrations and in an additional 4 at high concentrations (total 9 of 21, 42%). Concentration-dependent changes in the ventricular effective refractory period of the beat induced by S_3 paralleled antiarrhythmic efficacy. Independent of response or lack of response to intravenous quinidine, 17 patients received gradually increasing oral quinidine dosages adjusted to reproduce plasma levels that had been effective during intravenous administration, or to maximal well-tolerated dosage (if side effects occurred). VT was still inducible during oral treatment in 4 of 5 patients in whom VT had been suppressed during the intravenous infusion. Side effects frequently limited oral dosage to less than that required to reproduce effective concentrations. However, 2 patients did not respond to oral quinidine even when concentrations were equal to those which had been effective during intravenous treatment. In contrast, 11 of 12 patients who did not respond to intravenous quinidine also did not respond to its oral preparation. Response to intravenous quinidine also accurately predicted whether response would ultimately occur to any oral antiarrhythmic agent. In conclusion, acute drug testing to quinidine is safe and efficacious. The discrepancy between antiarrhythmic response to oral and intravenous quinidine is due, at least in part, to poor patient tolerance of large doses of quinidine given orally.

(Am J Cardiol 1985;55:92–97)

Although quinidine is effective treatment for some patients with atrial and ventricular tachyarrhythmias, intravenous use of quinidine has been traditionally considered hazardous because of frequent adverse side effects,[1–3] particularly hypotension at peak concentrations. Recent reports have suggested that the use of intravenous quinidine gluconate is not as troublesome as was alleged,[4–6] although hypotension continued to occur frequently in the study of Swerdlow et al.[6] The ability to administer intravenous quinidine safely and achieve a range of therapeutic plasma concentrations would allow a rapid and systematic evaluation of its antiarrhythmic efficacy in individual patients. A computer-simulated infusion was devised to produce pseudo-steady-state concentrations in the low and high therapeutic range with little overshoot. Using this

infusion protocol, safety, efficacy and electrophysiologic actions of quinidine sulfate were assessed in 21 patients with sustained, inducible ventricular tachycardia (VT).

Methods

Standard infusion: Published pharmacokinetic parameters of quinidine gluconate in normal humans[7–9] were used to design a standard series of infusions producing serum concentrations which gradually increased after an exponential growth pattern to minimize early peaks and troughs. This objective was achieved by giving a series of infusions at decremental rates (Fig. 1). The first series of infusions was designed to produce plasma concentrations in the low therapeutic range (approximately 8 μM/liter). If efficacy was not seen with these low-dose infusions, a second series of infusions was given to produce concentrations in the high therapeutic range (approximately 14 μM/liter). Because volume of distribution of a number of antiarrhythmic drugs, including quinidine,[8] is altered in the presence of congestive heart failure, radionuclide angiograms were performed in a drug-free state so that observed pseudo-steady-state plasma concentrations could be related to baseline ejection fraction (EF).

Protocol: Twenty-one patients with sustained, inducible VT were candidates for this study. These patients were referred for treatment due to: (1) sustained VT; (2) documented nonsustained VT (more than 5 consecutive ventricular ectopic depolarizations at a cycle length of less than 500 ms) that was associated with unmonitored outpatient syncope or that required cardiopulmonary resuscitation; or (3) syncope of obscure origin in patients in whom sustained unimorphic VT could be induced at electrophysiologic study. Sustained VT was defined as consecutive ventricular premature complexes at a cycle length of less than 500 ms lasting longer than 30 seconds, or producing hemodynamic compromise requiring termination of the tachyarrhythmia within 30 seconds.

Each patient gave written, informed consent. After withdrawal of all antiarrhythmic medications (for at least 4 half-lives), programmed electrical stimulation studies were done in a drug-free state. The standard quinidine sulfate infusion was then administered and blood pressure, pulse and clinical status were evaluated every 5 minutes throughout the infusion. Programmed electrical stimulation studies during the first series of infusions were not begun until the infusions had been under way for at least 40 minutes. Blood samples for quinidine assay were obtained just before and after electrophysiologic measurements. When VT induction was not suppressed with the first series of infusions, the higher dose infusion protocol was administered and electrophysiologic studies were repeated no sooner than 30 minutes after beginning the second series of infusions.

Independent of response to intravenous quinidine, consenting patients subsequently received gradually increasing oral dosages of quinidine. The dosage was adjusted to reproduce the serum levels that had been effective during the intravenous quinidine electrophysiologic study or to the maximal tolerated oral dose, whichever was lower. Electrophysiologic testing was then repeated on oral quinidine therapy.

Electrophysiologic studies: The ventricular origin of the patient's arrhythmia was confirmed by His bundle recordings. Programmed electrical stimulation techniques used in the study included introduction of single, double and, if necessary, triple extrastimuli (3 mA or twice diastolic threshold, whichever was greater, and a 2-ms pulse width) at ventricular drive cycle lengths of 600, 500 and 400 ms with the electrode catheter at the apex of the right ventricle.[10] Ventricular burst pacing (4 to 12 beats at cycle lengths of 300 to 240 ms) was subsequently used if VT was not induced by the extrastimulus

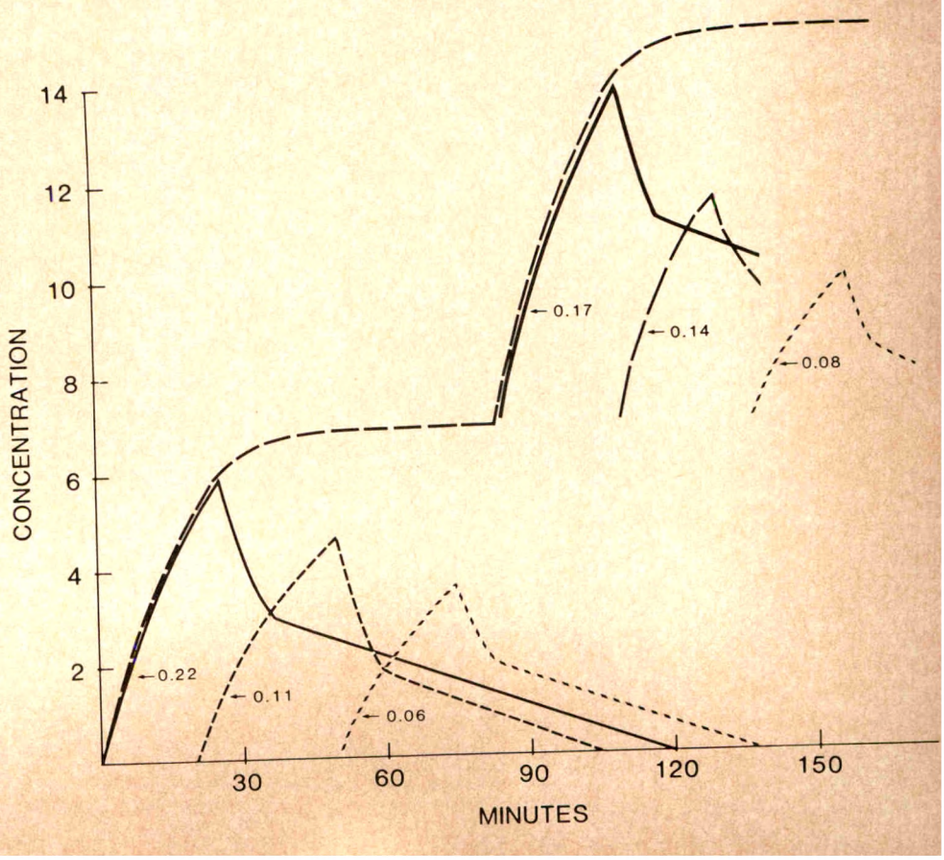

FIGURE 1. A decremental series of infusions produce concentrations that increase in a slow exponential pattern. Low therapeutic plasma concentrations are produced by infusion rates (μg/kg/min, each for 25 minutes) of 0.22, 0.11, 0.06 and higher concentrations by rates of 0.17, 0.14, 0.08.

technique. During the drug-free study the endpoint of programmed electrical stimulation was induction of VT on at least 2 occasions with at least 1 of these being sustained (defined above). During subsequent quinidine studies, the ability to induce at least 5 consecutive ventricular ectopic depolarizations at a cycle length of less than 500 ms was considered to be drug failure.

Concentration-dependent change in other electrophysiologic parameters were also evaluated. Surface electrocardiographic leads I, aVF and V_1 were recorded at baseline and during quinidine treatments, and the PR, QRS, QT and RR intervals were measured. Rate-corrected QT (QTc) was calculated from the formula $QTc = QT/\sqrt{RR}$. Ventricular effective refractory periods (VERPs) of the beats induced by the first and second extrastimuli (S_2, S_3) were also measured using the extrastimulus technique and conventional definitions. Concentration-dependent changes in rate and morphologic pattern of the induced VT were also assessed.

Analytical: Samples were assayed, using an enzymatic immunoassay (EMIT®) method. The therapeutic range for quinidine has been reported to be 7 to 14 μM/liter. Little cross-reactivity to quinidine's major metabolite has been found using this assay.[11,12]

Statistics: One-way analysis of variance was used to assess the significance of changes in electrophysiologic measurements during the quinidine infusions. Chi-square analysis was used for discrete data. The null hypothesis was rejected at the $p < 0.05$ level. Continuous data are presented as mean ± standard deviation.

Results

Patients: Four of the 21 patients had 1 or more episodes of ventricular fibrillation, 9 had spontaneous sustained VT, 5 had nonsustained VT and recurrent outpatient syncopal episodes and 3 were evaluated for syncope of obscure origin. Six of the 21 patients had required 1 or more transthoracic cardioversions for VT and 4 of the patients had required cardiopulmonary resuscitation out of hospital. Seventeen of the patients had ischemic heart disease with a global EF of 42 ± 10%.

Quinidine infusion: The first series of quinidine infusions achieved pseudo-steady-state concentrations of 12.6 ± 11 μM/liter while the second series of infusions produced serum concentrations of 18 ± 9 μM/liter. Mean observed plasma levels were somewhat in excess of the target concentration (7 and 14 μM/liter), and there was substantial interindividual variation. Figure 2 shows a reciprocal linear relation between the drug-free EF and the observed plasma concentrations at electrophysiologic testing ($r = 0.8$, $p < 0.01$). Symptomatic hypotension was seen in 3 patients during the quinidine infusion. Hypotension was promptly corrected by administration of saline solution and did not require the termination of the infusion in any patient. There was no relation between likelihood of developing hypotension and clinical characteristics of the patients or observed serum concentration. Two of the 3 patients in whom hypotension developed had normal left ventricular EF. None of the 6 patients with EFs of less than 30% who were given the standard quinidine infusions had adverse effects.

Concentration-dependent antiarrhythmic and electrophysiologic changes: The antiarrhythmic activity of quinidine sulfate (as assessed by its ability to preclude induction of VT) increased with increasing serum concentrations (Fig. 3). Forty-three percent of the patients responded to intravenous quinidine, and little additional benefit was observed with serum concentrations in excess of 18 μM/liter. Induction of VT with a stimulation protocol which was less aggressive than that required at baseline occurred in 7 patients during the quinidine infusions. VT was easier to induce

in 4 of the 7 patients at low concentrations, while high-dose quinidine enhanced VT induction in 3 patients. Of interest, 2 of 4 patients in whom VT was easier to induce after low-dose quinidine infusion responded to the larger dose infusion with suppression of inducibility. There was no simple relation between extent of QTc prolongation or VERP change and ease of inducibility. While inducibility of VT was occasionally enhanced by quinidine, paradoxical acceleration of VT rate was not seen. Figure 4 illustrates concentration-dependent changes in electrophysiologic measurements. The VERP of S_2 was increased only to a small degree in these patients and there was little increase in this measurement at concentrations beyond 7 μM/liter. However, the VERP of the beat induced by S_3 progressively increased throughout the concentration range tested and paralleled antiarrhythmic efficacy. The relation between quinidine concentration and change in QRS was linear ($r = 0.62$, $p < 0.05$). A plateau in the concentration-dependent increase in QTc interval occurred at approximately 14 μM/liter. Although the cycle length of induced VT was slowed by quinidine (245 ± 53 ms at baseline; 313 ± 80 ms with low-dose quinidine, and 364 ± 62 with high-dose quinidine) the extent of its slowing did not correlate with serum concentration.

Response to intravenous quinidine as a predictor of response to oral treatment: Independent of the response to intravenous quinidine, 17 consenting patients received gradually increasing oral dosages of quinidine and electrophysiologic studies were repeated. Table I illustrates the relation between inducibility during intravenous quinidine treatment to inducibility during its oral administration. Four of 5 patients who responded to intravenous quinidine did not respond during oral treatment. In 2 of these 4 patients the oral quinidine dose was limited by side effects and the effective concentrations achieved with intravenous quinidine could not be reached. However, VT continued to be inducible during oral therapy in 2 patients who had equal plasma levels during intravenous and oral treatments (Table II). In contrast, the absence of antiarrhythmic response to intravenous quinidine accurately predicted a lack of response to oral quinidine in 11 of 12 patients.

We also assessed whether the antiarrhythmic response to intravenous quinidine would predict eventual response to any oral antiarrhythmic therapy (Tables II and III). Eight of 9 patients who responded to intravenous quinidine finally responded to oral antiarrhythmic medication (Table II). Nine of 12 patients who did not have an adequate antiarrhythmic response to intravenous quinidine did not respond to any oral medication.

Discussion

Acute electrophysiologic effects of intravenous quinidine have been previously investigated after stopping a rapid infusion of quinidine.[6,13,14] However, concentration-response relations measured during the rapid distribution phase may not be reliable.[15] Furthermore, in previous studies no attempt was made to systematically evaluate antiarrhythmic efficacy over the entire therapeutic range.[6] The rapid infusion technique also increases the likelihood of side effects by producing early high peak levels. Symptomatic hypotension occurred frequently in the study of Swerdlow et al,[6] but it was infrequently seen in the present study. Rapid evaluation of efficacy and pharmacologic actions of intravenous antiarrhythmic agents can be improved when infusions produce pseudo-steady-state serum

concentrations which explore concentration response relations over the entire therapeutic range without side effects.

The quinidine infusion devised for this study did achieve a range of therapeutic concentrations; however, other problems of acute drug testing limit its overall value. Antiarrhythmic effects seen during the acute drug infusion did not predict the response with oral quinidine treatment. Such discrepancies may relate to several factors, including: (1) side effects during chronic oral therapy, which limit dosage increments so that effective concentrations seen with the intravenous quinidine are not reached; (2) a difference in the relation between tissue levels and plasma levels when these are measured under pseudo-steady-state and steady-state conditions; and (3) the presence of active metabolites, which may contribute to pharmacologic actions and side effects. The relative inefficacy of oral quinidine in this study was primarily a result of side effects that limited our ability to reproduce effective plasma concentrations during the infusion. Side effects seen with oral quinidine treatment may reflect local gastrointestinal irritation. Chou[16] evaluated the relation between plasma concentrations and ventricular tissue concentrations of quinidine during a constant infusion in dogs. In that study, there was little discrepancy between intravenous and myocardial concentrations after 90 minutes, suggesting that there is little difference in tissue levels under pseudo-steady-state and steady-state conditions. Two patients did not respond to oral quinidine, even though their plasma levels reproduced concentrations that had been effective during intravenous quinidine therapy. Hypothetically, active metabolites of quinidine could accumulate during long-term oral therapy and as the metabolites are electrophysiologically active[17,18] they could alter antiarrhythmic efficacy.

The infusions designed for this study allowed an evaluation of concentration-related changes in electrophysiologic parameters and their relation to antiarrhythmic activity. No single electrophysiologic change or combination thereof clearly discriminated between patients who would or would not respond to quinidine. However, we noted that change in the VERP of the beat induced by S_3 had a concentration-response relation that paralleled antiarrhythmic activity. Although parallel concentration-response curves do not indicate a cause and effect relation, such observations do suggest potentially fruitful areas of future research. Few other studies in man have systematically evaluated the concentration-response relations of electrophysiologic changes with quinidine. The present data, like previous data from human studies by Heissenbuttel and Bigger,[19] show concentration-dependent changes in QRS duration, QTc interval. Unlike Heissenbuttel's study[19] we evaluated change in VERP (S_2) and observed that its increase occurs at low plasma concentrations (7 μM/liter) with little increase in this measurement at higher concentration. The QTc interval however progressively prolonged and only then plateaued at approximately 12 μM/liter, while QRS increases linearly with concentration. Varying concentration-response relations suggest that quinidine may mediate its elec-

TABLE III Inducibility (I) or Noninducibility (NI) of Tachycardia with Quinidine Compared with Any Oral Antiarrhythmic Agent

$p < 0.01$ (χ^2).

trophysiologic actions at a number of different active sites. These results are in keeping with in vitro data[20] that suggests that quinidine's effects on various phases of the action potential are mediated at a number of active sites.

The results obtained with intravenous quinidine in this study are similar to those seen with procainamide. As with procainamide,[21,22] high concentrations of quinidine achieved control of ventricular arrhythmias resistant to more conventional concentrations and acute toxicity at high concentrations was not a major problem.[22,23] Despite the limitation of use of acute intravenous quinidine testing to predictive response to oral quinidine, such testing may be of value in predicting eventual response to any oral antiarrhythmic agent. A similar predictive value[22,23] has been seen relating antiarrhythmic response to procainamide and response to any oral antiarrhythmic agent. Differences are also apparent between quinidine and procainamide. In this study, oral quinidine therapy was not well tolerated, unlike results reported with high-dose oral procainamide.

This infusion was designed from pharmacokinetic parameters derived from administration of intravenous quinidine gluconate. The administered dosage was then adjusted to reflect the relative proportion of the quinidine sulfate molecule, which is base (rather than salt). Theoretically, if the present quinidine infusion were modified so that quinidine gluconate was to be given, the serial intravenous rates would be increased by a factor of 1.34.

In conclusion, an infusion protocol for the administration of quinidine sulfate was devised that permits a rapid and safe assessment of antiarrhythmic efficacy at both low and high therapeutic concentrations in man. Response to intravenous quinidine predicts the likelihood of a response to any oral antiarrhythmic agent. However, this infusion has a major limitation relating to a discrepancy between tolerance to intravenous and oral medication.

Effect of the Calcium Antagonist Diltiazem on Atrioventricular Conduction in Chronic Atrial Fibrillation

KARL THEISEN, MD, MATHIAS HAUFE, MD, JOCHEN PETERS, FRANZ THEISEN, MD, and HANS JAHRMÄRKER, MD

The effect of oral diltiazem treatment on the mean ventricular rate was studied in 10 patients with stable atrial fibrillation (AF). The profile of mean ventricular rate was analyzed by means of 24-hour electrocardiographic recordings. Both single-dose (120 mg) and maintenance therapy (80 mg 3 times daily) reduced the mean ventricular rate significantly. After the single dose, the effect set in after 120 ± 40 minutes (mean ± standard deviation) and persisted for 347 ± 84 minutes. Histograms of RR intervals were plotted and their changes after diltiazem therapy were also analyzed. The shortest and longest atrioventricular (AV) conduction times were defined as 5% and 95% values of the cumulative frequency curve, respectively. There were 2 distinct types of the RR-interval histographic changes: In 50% of the patients, the longest and shortest RR intervals prolonged proportionately; in the other 50%, the longest intervals increased disproportionately. Results indicate that oral diltiazem treatment can significantly decrease the mean ventricular rate in patients with AF by influencing the concealed conduction in the AV node. The changes of the RR-interval histograms suggest that in 50% of the patients, the increase of the concealed conduction was probably caused primarily by the increase of AF rate, and in 50% both increased AF rate and prolonged refractory period in the AV node contributed to the increase of concealed conduction.

(Am J Cardiol 1985; 55:98–102)

Diltiazem is a slow channel blocking drug.[1] In contrast to the calcium antagonist nifedipine, diltiazem has marked antiarrhythmic effects, similar to those of verapamil.[2–4] In clinical studies, verapamil[5] and diltiazem[6] reversed supraventricular tachycardias. In cases of atrial fibrillation (AF), intravenous[5,7] and oral[8] administration of verapamil, as well as intravenous diltiazem,[9] reduced the mean ventricular rate. The present study assesses the oral effectiveness of diltiazem on the basis of ventricular rate reduction in patients with stable AF. The extent of ventricular rate depression, onset and duration of action, and indications of the mechanism of action were studied.

Methods

Patients: The test group included 10 patients (8 women, 2 men), aged 39 to 81 years. All patients had had stable AF over an extended time. Clinical diagnoses of the patients are shown in Table I. Eight of the 10 patients were taking digitalis maintenance therapy with effective levels in the standard range. None of the patients were treated with other drugs that act on the atrioventricular (AV) node or with other antiarrhythmic agents. All patients were in a clinically stable condition and had given informed consent.

Protocol: Each patient received a single oral dose (120 mg) of diltiazem, and 10 hours later maintenance therapy was initiated (90 mg 3 times daily), and was continued for at least 4 days.

Twenty-four hour electrocardiograms (ECGs) were recorded (Reynolds Pathfinder II system) before treatment (control phase), at the beginning of treatment, and after 3 days of medication. The second 24-hour ECG contained the response of the patients after the single 120-mg dose of diltiazem and at the beginning of the maintenance therapy (90 mg 3 times daily), initiated 10 hours later. The third 24-hour ECG showed the steady-state response of the patients receiving maintenance therapy. From the 24-hour ECGs, the mean ventricular rate was plotted (Fig. 1) and plotting RR-interval histograms for any desired period was also possible (Fig. 2). The onset of action, defined as the point at which 50% of the maximal rate of depression is reached, and the cessation of action, defined as the point at which the 50% maximal rate depression is no longer maintained, were determined in the acute test after the administration of 120 mg of diltiazem (Fig. 1). In the comparison of the control phase and the maintenance phase with 90 mg 3 times daily, both the absolute values of the RR intervals and the mean ventricular rates were used. The 5% and 95% values of the cumulative frequency curves of the RR intervals were defined as the shortest and longest

AV conduction times, respectively. These values are referred to as fifth and ninety-fifth percentiles in this report. Short RR intervals (represented by the fifth percentile) were taken as measure of the AV refractory period. Prolongation of the long RR intervals (represented by the ninety-fifth percentile) were taken as a measure of the increase in concealed conduction (Fig. 2). The changes of the fifth and ninety-fifth percentile values of the RR-interval histograms were also compared in the control and maintenance phases. (Table II, Fig. 3). Blood levels of diltiazem have been determined in 8 of the 10 patients 90 minutes after oral administration of 120 mg of diltiazem (Table III). Throughout the acute test blood pressure was checked at regular intervals of 1 to 2 hours. Routine clinical examinations and clinical chemistry tests were performed before the investigations.

Results

Ventricular rate reduction in the acute test after 120 mg of diltiazem: After oral administration of 120 mg of diltiazem, a significant ($p < 0.001$) reduction in the mean ventricular rate was achieved in all patients (Table III). The mean (± standard error of the mean) reduction in ventricular rate was 30 ± 5%. The onset of action occurred after 120 ± 40 minutes (range 60 to 180). The duration of action was 347 ± 84 minutes (range 220 to 520). The duration of action was not determined for patient 7 because of technical difficulties. Plasma levels of diltiazem between 17 and 75 ng/ml were found in 7 patients. In 2 patients these values could not be determined. In patient 9, a plasma level of 2 ng/ml was measured.

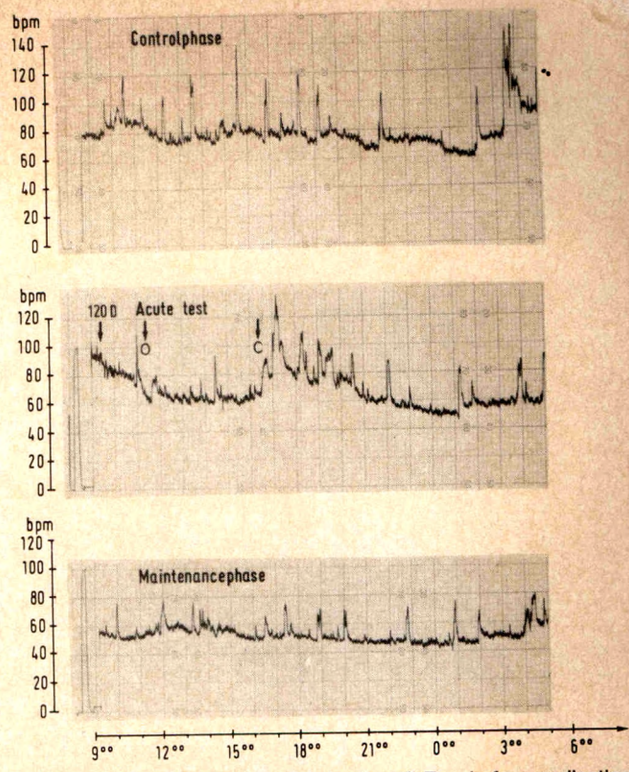

FIGURE 1. Mean ventricular rate of patient 6. **Top,** before medication (control phase). **Middle,** acute effect of diltiazem. A dose of 120 mg was given orally (**arrow**). After onset of action (O, defined as the point when 50% of the maximal rate depression has been reached), the mean ventricular rate remains less than control value for several hours. After cessation of action (C, defined as the point when the 50% maximal rate depression is no longer maintained), the curve returns to the premedication range. After maintenance therapy (90 mg 3 times daily) has been initiated (at 18 hours), the curve drops again. **Bottom,** after 3 days of maintenance therapy, the maintenance phase values remained consistently below the control level. Peaks with relatively rapid heart rate also fell below control values.

Ventricular rate reduction after oral maintenance therapy: The mean ventricular rate was reduced significantly ($p < 0.001$), in patient 4 by 5% and by 11 to 34% in the rest of the patients. The absolute number of

In patients 2, 3, 4, 8 and 10 the longest RR intervals increased more than the shortest.

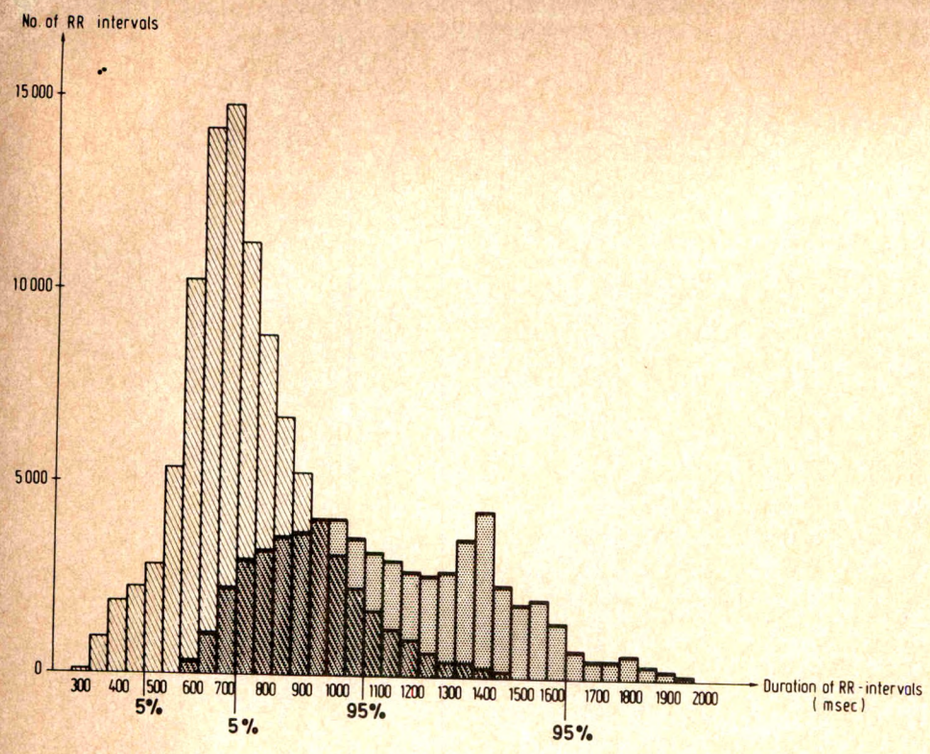

FIGURE 2. RR-interval histograms of patient 6. The recording time is 21 hours, 15 minutes. The **thin border** represents the control phase before medication and the **heavy line** represents the maintenance phase after 3 days of treatment with 90 mg 3 times daily. Fifth percentile values are taken as shortest and ninety-fifth percentile values as longest RR intervals.

RR intervals also decreased after maintenance therapy (Fig. 4, Table IV).

Effect on the fastest and on the slowest atrioventricular conduction times: The shortest (fifth percentile) and longest (ninety-fifth percentile) RR intervals increased proportionately in 5 patients; however, in 5 patients the long RR intervals increased more than the shortest ones (Fig. 3, Table II).

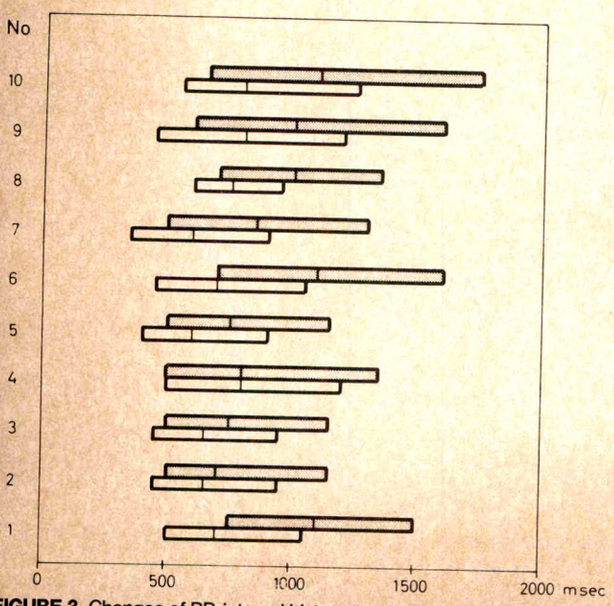

FIGURE 3. Changes of RR-interval histograms in the 10 patients studied. **Clear** and **shaded bars** represent control and maintenance phase histograms, respectively. The **horizontal columns** show only the characteristic parameters of the histograms: **left,** fifth percentile; **middle,** median value; **right,** ninety-fifth percentile.

Adverse effects: Patients 1 and 3 had a slight decrease in blood pressure during the acute test, but discontinuation of the therapy was not necessary. Pronounced cases of bradycardia were not observed. One of the 10 patients initially complained of fatigue. No further adverse effects were detected in the laboratory tests.

Discussion

In AF, the mean ventricular rate is determined by the extent of concealed conduction.[10–13] Owing to diminishing conduction and the formation of blocks, some atrial impulses penetrate in the AV node to varying degrees, without being conducted to the ventricle. According to Moe and Abildskov,[11] 2 factors determine the extent of concealed conduction: the AF rate, as input to the upper AV node, and the duration of the zone of concealment (ZOC). ZOC is the period after an atrial excitation during which concealed conduction can take place. Concealed conduction results in reduced conduction of atrial stimuli. It is the result of the complex 3-dimensional structure and of the electrophysiologic properties of the AV node cells.[14] The ramifications of these cells render summation, functional longitudinal dissociation and inhomogeneous fractionation of the propagating waves possible when several wave fronts coincide in AF, resulting in slow conduction and block formation.[15–17] In addition, local reentry phenomena are stimulated by the "blind cells."[18] The ZOC is not constant during AF. Although it depends on the refractory period of the AV node, the 2 variables are more or less equivalent only in very short RR intervals, when minimal or no concealed conduction takes place.[11,12] His bundle electrocardiographic studies of patients with AF indicate that the ZOC is essentially localized proximally to the His bundle.[19] Decreased conductivity would [illegible]

10	22.30	94,028 (71)	71,929 (53)	24

formation has been shown in the so-called AN and especially in the N regions of the AV node.[14,15] In the N region are calcium-influx-dependent, slow-response action potentials.[14,20] Calcium antagonists such as verapamil prolong AV conduction by acting on the slow-response action potentials of the AV node,[21–23] resulting in prolonged PR or AH intervals in sinus rhythm.[3,24] Verapamil therapy prolonged the functional refractory period of the AV node more than diltiazem.[25]

Intravenous diltiazem treatment causes a decrease in the mean ventricular rate in patients with AF.[9] In the 10 patients of this study, the mean ventricular rate was reduced significantly by a 120-mg single oral dose of diltiazem, as well as by maintenance treatment of 90 mg 3 times daily. It is concluded that reduction of the mean ventricular rate is possible by increasing concealed conduction in the AV node with oral administration of diltiazem, as with verapamil. The histogram of the RR intervals was analyzed to study the underlying mecha-

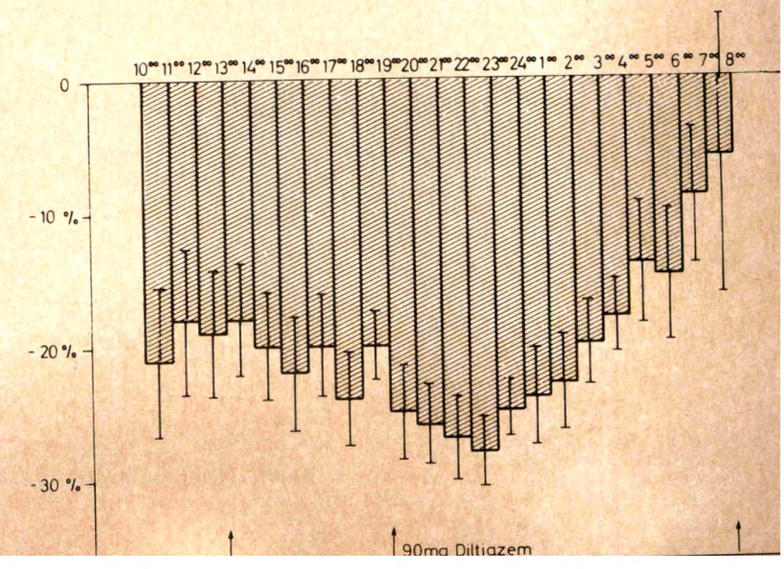

FIGURE 4. Changes of the RR intervals after diltiazem therapy for 3 days (90 mg 3 times daily). Average RR intervals have been calculated for each 1-hour interval for each patient. These are compared to the respective control values (before treatment). The depth of the columns represent the mean decrease of the heart rate in the 10 patients studied; bars show the standard deviation. Apparently the effect of the evening dose given at 7 PM does not last until next morning.

nism of the reduction of the mean ventricular rate. According to Moe and Abildskov,[11] the extent of concealed conduction is proportional to the duration of the ZOC and to the AF rate. Therefore, an increase in concealed conduction is furthered by an increase in AF rate and by the prolongation of the ZOC. An increase in concealed conduction in the AV node results in more excitations blocked and in longer and less regular RR intervals. Accordingly, the longest RR intervals contain a high proportion of concealed conduction, whereas the shortest RR intervals contain much less or no concealed conduction. The shortest RR intervals are largely determined by the functional AV refractory period, and coincide with it when there is no concealed conduction.[11] Consequently, the change of the RR-interval histogram after treatment may yield some information about the mechanisms involved.

In animals, influencing AV conduction by vagal stimulation results in enhancement of concealed conduction. AF rate, and consequently the number of impulses entering the AV node, increases as a result of the reduced atrial refractory period. The ZOC also increases; however, the functional refractory period of the AV node remains largely unchanged. This leads to a decrease in mean ventricular rate, while the RR intervals become longer and less regular. Yet the shortest RR intervals, which have little or no concealed conduction, do not disappear.[11] Digitalis exerts a similar influence on AV conduction in AF.[26] Adrenergic influence accelerates AV conduction and reduces the ZOC, and the ventricular rate becomes more rapid and regular.[11]

In this study, 50% of the patients responded to diltiazem maintenance therapy with proportional changes of the longest (ninety-fifth percentile) and shortest (fifth percentile) RR intervals, whereas the rest of the patients responded with a disproportionate increase of the longest RR intervals. After the administration of diltiazem, a shift of the shortest RR intervals to the right in the spectrum of an absolute arrhythmia suggests a change of the AV nodal refractory period, since the shortest RR intervals contain little or no concealed conduction. However, a proportional shift of the longest intervals suggests an increase in concealed conduction. The latter can be caused by accelerated AF rate or by an increase of the ZOC. A disproportionate increase of the longest RR intervals could be then attributed to increased concealed conduction. Since the shortest RR intervals reflecting the functional AV refractory period change less, the increase of concealed conduction is probably caused by accelerated atrial rate. This mechanism would resemble experimental vagal stimulation. However, proportionate change of the shortest and longest RR intervals suggest a similar increase of both AF rate and the AV nodal refractory period.

Influencing the AF rate in diseased atria by means of calcium antagonist drugs may be possible, since slow response action potentials have also been demonstrated there.[27] AF is generally caused by reentrant activity in the atrial region.[28] The extent to which calcium antagonists cause accelerated circulatory excitation and increased atrial rate is not well known. In the ischemic, damaged ventricular myocardium, verapamil has been shown to improve conduction, probably influencing depressed fast-response action potentials.[29] With diltiazem treatment, a decreased functional refractory period has been shown in the human atrium, which may result in accelerated conduction.[25] After administration of diltiazem we noted no pseudoregularization of the RR intervals in AF, as observed after administration of large doses of verapamil, and attributed to a possible total AV block and activity in an ectopic ventricular center.[5]

Electrocardiographic Diagnosis of Left Ventricular Hypertrophy in the Presence of Left Bundle Branch Block: An Echocardiographic Study

HENRYK KAFKA, MD, GARY W. BURGGRAF, MD, and JOHN A. MILLIKEN, MD

This study tests the electrocardiographic diagnosis of left ventricular (LV) hypertrophy in the presence of left bundle branch block (BBB). The LV mass of 125 patients with left BBB was estimated by echocardiography. M-mode echocardiography was technically adequate in 80% of patients. LV mass was calculated using previously validated M-mode formulas and then indexed to body surface area. The known shifts in the QRS voltage and axis with the onset of left BBB led to the selection of 4 electrocardiographic parameters for the diagnosis of LV hypertrophy: R in aVL 11 or more; QRS axis −40° or less (or SII >RII); $SV_1 + RV_5$ to RV_6 40 or more; SV_2 30 or more and SV_3 25 or more; these parameters were used in cumulative fashion. This cumulative approach was superior to using single conventional criterion such as the $SV_1 + RV_5$ or RV_6. When LV hypertrophy was defined as an M-mode index of at least 115 g/m², the sensitivity was 75% and specificity 90%. Using an M-mode mass of at least 215 g as the standard, the sensitivity was 73% and the specificity 66%. LV hypertrophy can be diagnosed by electrocardiographic criteria in the presence of left BBB at least as reliably as in normal conduction.

(Am J Cardiol 1985;55:103–106)

The presence of left bundle branch block (BBB) is believed, by most electrocardiographers, to invalidate the usual criteria for left ventricular (LV) hypertrophy. However, several autopsy studies indicate that the commonly used criteria, as in normal conduction, remain specific but insensitive.[1–4] Since necropsy studies usually have few hearts of normal size, this tends to limit the usefulness of their conclusions. Both M-mode and 2-dimensional (2-D) echocardiography have been demonstrated to be valid methods for estimating LV mass.[5,6] Their use in patients with normal conduction suggests that the Romhilt-Estes point score[7] and the Sokolow-Lyon voltage criteria for the electrocardiographic diagnosis of LV hypertrophy are insensitive, although highly specific.[8,9] In most studies that evaluate electrocardiographic criteria for LV hypertrophy, those with prior myocardial infarction or left BBB are excluded because such disorders are believed to impair the electrocardiographic recognition of LV hypertrophy.[8,9] This study assesses the validity of electrocardiographic criteria in the diagnosis of LV hypertrophy in the presence of left BBB using echocardiographically determined LV mass as the standard.

Methods

Study patients: The study group consisted of 125 patients (51 women, 74 men) with left BBB, aged 34 to 98 years (mean 66). The patients were selected from the electrocardiographic files of Hotel Dieu Hospital in 1982. Two hundred seventy-six patients were identified in this fashion, but only 125 could be recalled for echocardiography and a repeat electrocardiogram. Twenty-two of the 125 patients were clinically normal, 56 had suspected coronary artery disease, 16 had idiopathic cardiomyopathy, 10 had valvular heart disease, 16 had hypertension and 5 had other cardiac problems.

Another group of 41 clinically normal subjects with normal electrocardiograms were examined to establish a normal value for LV mass.

Electrocardiographic analysis: All electrocardiograms were recorded with either a Marquette Mac I or Mac II cart using multichannel simultaneous leads. The criteria used for selection of left bundle branch block were: QRS duration 120 ms or longer; broad, slurred R waves in leads I, aVL and V_6; and broad, slurred S waves in V_1 and V_2 (QS or rS). All electrocardiographic measurements were made manually and entered into the computer for subsequent analyses. The R and S waves of all 12 leads were carefully measured and recorded, averaging, where necessary, to the nearest 0.1 mV or mm. Axis

TABLE I Mean Left Ventricular Mass in 41 Normal Subjects and 100 Subjects with Left Bundle Branch Block

	Normal Subjects		Left BBB Subjects	
	M-Mode Mass (g)	M-Mode Mass Index* (g/m^2)	M-Mode Mass (g)	M-mode Mass Index (g/m^2)

direction was calculated from the limb lead measurements and recorded to the nearest 5° interval. The presence of left atrial enlargement[7] was independently diagnosed by 2 readers. The Lewis index [(RI − SI) + (SIII − RIII)], Sokolow-Lyon score ($SV_1 + RV_5$ or RV_6) and the Selvester score[10] were all calculated.

Echocardiographic technique: Echocardiograms were obtained with a Hewlett-Packard phased-array instrument (model 77020A) using a 2.5-MHz transducer. The LV mass was then calculated by the method of Reichek and Devereux,[8] and we defined LV hypertrophy as they did: LV mass of at least 215 g.[8] Rather than using only 1 value for LV mass, for both sexes and all ages, we also corrected for body size by dividing the calculated M-mode mass by the body surface area. LV hypertrophy was then defined as an M-mode mass index of at least 2 standard deviations of the mean mass index of our 41 normal subjects (Table I)—≥ 115 g/m^2.

Statistical methods: The sensitivity and specificity of various electrocardiographic criteria for LV hypertrophy were calculated using standard formulas: sensitivity (%) = (true-positives correctly diagnosed/total true positives) × 100; specificity (%) = (true-negatives correctly diagnosed/total true negatives) × 100.

Results

Satisfactory M-mode echocardiograms were obtained in all 41 normal subjects. The LV mass values for the normal subjects ranged from 75 to 215 g (mean ± 1 standard deviation 150 ± 35). The mean LV mass was lower for women than for men, but the use of the LV mass index eliminated this difference. Among those with left BBB, men had a much higher mean LV mass (315 g) than women (201 g). This difference was also reduced when the mass index figure was used: men, 168

g/m^2; women, 125 g/m^2. The mean figures for the left BBB group exceed the upper normal range by a considerable margin, resulting in 56% with an LV mass of 215 g or more and 71% with a mass index 115 g/m^2 or more.

Electrocardiographic criteria: The sensitivity and specificity of the various electrocardiographic parameters in the detection of LV hypertrophy is contained in Table II. Good overall single parameters were $SV_3 \geq 25$ (sensitivity 56% and specificity 90%) and $R + S \geq 40$ (sensitivity 63% and specificity 66%). A QRS duration of 0.16 or higher was very sensitive (75%), but specificity was low, 34%. Using the M-mode mass index of at least 115 g/m^2 as the standard for increased LV mass, various combinations of criteria were selected from Table II and used in cumulative fashion. Intermittent left BBB is known to alter voltage and shift electrical axis to the left, which led to the selection of 4 electrocardiographic parameters (Fig. 1).

Table III shows the effects of combining 4 criteria in cumulative fashion. Two criteria from the limb leads (R in aVL 11 or more and QRS axis −40 or less or SII > RII) correctly diagnosed 39% of those with LV hypertrophy with 100% specificity; and 17% were not detected by the subsequent use of chest lead measurements. Two chest lead measurements, Sokolow-Lyon index 40 or more and $SV_2 \geq 30$ and SV_3 25 or more, correctly labeled 56%, with a specificity of 93%. When any of these 4 parameters was accepted as a diagnosis of LV hypertrophy, the sensitivity was 75% and specificity 90%. If an LV mass 215 g or more was required as a standard, then the sensitivity remained at 73% but the specificity fell to 66%. The use of criteria for left atrial abnormality added only 3% to the sensitivity values with no loss of specificity.

TABLE III The Cumulative Percentage Sensitivity and Specificity for Left Ventricular Hypertrophy in Left Bundle Branch Block Using 4 Electrocardiographic Variables (n = 100)

Left Ventricular Hypertrophy	M-Mode Mass ≥215 g 56% Sens/Spec	M-Mode Index ≥115 g/m^2 71% Sens/Spec
RaVl ≥11 mm	21/89	24/100
Axis ≤−40° (or SII > RII)	34/80	39/100
$SV_1 + RV_5$ or $RV_6 \geq 40$ mm	55/75	58/97
$SV_2 \geq 30$ and $SV_3 \geq 25$ mm	73/66	75/90

Discussion

In 1951, Pantridge[11] used clinical assessment for proof of LV hypertrophy and concluded that the electrocardiographic criteria for left BBB with LV hypertrophy were not altered from those used in normal conduction. Most of the later studies have been limited to autopsied cases and contain few patients with a normal LV mass.[1–4,11,12] They are unlikely to be representative of the live population with left BBB. By using an echocardiographic standard, we could include patients with a wide range of LV weights. Many were normal; 44% had an LV mass of less than 215 g and 29% had a normal M-mode mass index of less than 115 g/m^2. This is in keeping with previously reported studies of ambulatory military patients with left BBB.[13,14]

In 1978, Lopes et al[15] studied 30 patients with left BBB by means of M-mode echocardiography and calculated the LV mass. In 23 patients with an abnormal left ventricle, the LV mass averaged 241 ± 12 g. The 7 patients with a normal left ventricle had an LV mass of 138 ± 6 g. The Sokolow-Lyon score diagnosed 19 of 23 (82%) with 2 false-positive results. Five patients had intermittent left BBB and all had an increase in SV_1 and a decrease in RV_5 and RV_6 when left BBB was present. The Sokolow-Lyon score, however, was unaltered.

Recently, Noble et al[16] used M-mode echocardiography to determine the prevalence of anatomic LV hypertrophy in 28 patients with left BBB. They found anatomic LV hypertrophy (defined as LV mass of 215 g or more) in 89% of their patients and left atrial abnormality detected 58%, with 100% specificity.

When left BBB occurs, both the QRS voltage and the QRS axis change from that seen during normal conduction. By reviewing 79 cases of intermittent left BBB, Cokkinos et al[17] found a statistically significant reduction in R-wave voltage in leads I, V_5 and V_6 and an increase in the S-wave voltage in V_1 and V_2 plus a leftward shift in the QRS axis. These changes apparently did not affect the Sokolow-Lyon score, so they concluded that this score was just as useful as in normal conduction. However, a Sokolow-Lyon value of more than 35 developed in 25%, thus reducing the specificity. The change in QRS axis was reported to be of little help.

Since LV mass may depend on body size,[18,19] it was indexed to body surface area. Our upper limit for a normal mass index by M-mode echocardiography, 115 g/m^2, compares with the value of 119 g/m^2 reported by others.[20] Despite the concern about the effect of body size on heart weight, Reichek and Devereux[8] used a value of 215 g for defining LV hypertrophy in their echocardiographic study of patients with normal conduction. We therefore used this criterion in our study.

Our sensitivities and specificities of individual variables in the detection of LV hypertrophy are similar to those reported by others[4,8,21] (Table IV). This confirms that electrocardiographic criteria are as valid in the presence of left BBB as they are in normal conduction. Most previous studies have used only individual electrocardiographic variables and never combined them cumulatively like the usual reader. Our 4 criteria all exceed the 98th percentile normal ranges studied and reviewed recently by Murphy et al.[22] The voltage shifts known to occur in left BBB undoubtedly enhance the validity of these measurements. This and the marked increase in LV mass in many of our BBB patients may account for our higher sensitivity.

Recently Teichholz et al[23] used stepwise discriminant analysis to improve the electrocardiographic criteria for the diagnosis of LV hypertrophy in normal conduction.

TABLE IV Comparison of Selected Electrocardiographic Criteria for Left Ventricular Hypertrophy in Left Bundle Branch Block and in Normal Conduction

	Echo Studies		Autopsy Studies	
	Present Study—Left BBB, LV Mass ≥215 g Sens/Spec	Reichek[8]—Normal Conduction, LV Mass ≥215 g Sens/Spec	Havelda[4]—Left BBB, LV Weight >250 g Sens/Spec	Romhilt[21]—Normal Conduction, LV Weight >175 g Sens/Spec
R aVL ≥11	21/89	47/99	36/83	13/99
Lewis index ≥17	38/75		34/100	18/98

Left atrial enlargement	41/98	47/91		48/95*
Left axis ≤−30	30/75	33/97	39/91	24/87

* From Romhilt and Estes.[7]

Their sensitivity increased from 42% to 78%, while specificity decreased from 86% to 76%. They had comparable results when their program was retested in a new group of patients. Multivariate discriminant analysis may also help in left BBB.

By using 4 relatively simple electrocardiographic measurements, one should be able to diagnose LV hypertrophy in the presence of left BBB with a sensitivity of 75% and specificity of 90%. These criteria must be tested in a new group of cases with left BBB.

Acknowledgment: We thank Rose Norman for her technical assistance in performing the echocardiographic studies and Elizabeth Milliken for assistance with statistical analyses and typing the manuscript. We acknowledge the advice of Dr. Sally Ford regarding anatomic left ventricular hypertrophy and the cooperation of the family physicians of Kingston who so kindly allowed us to study their patients.

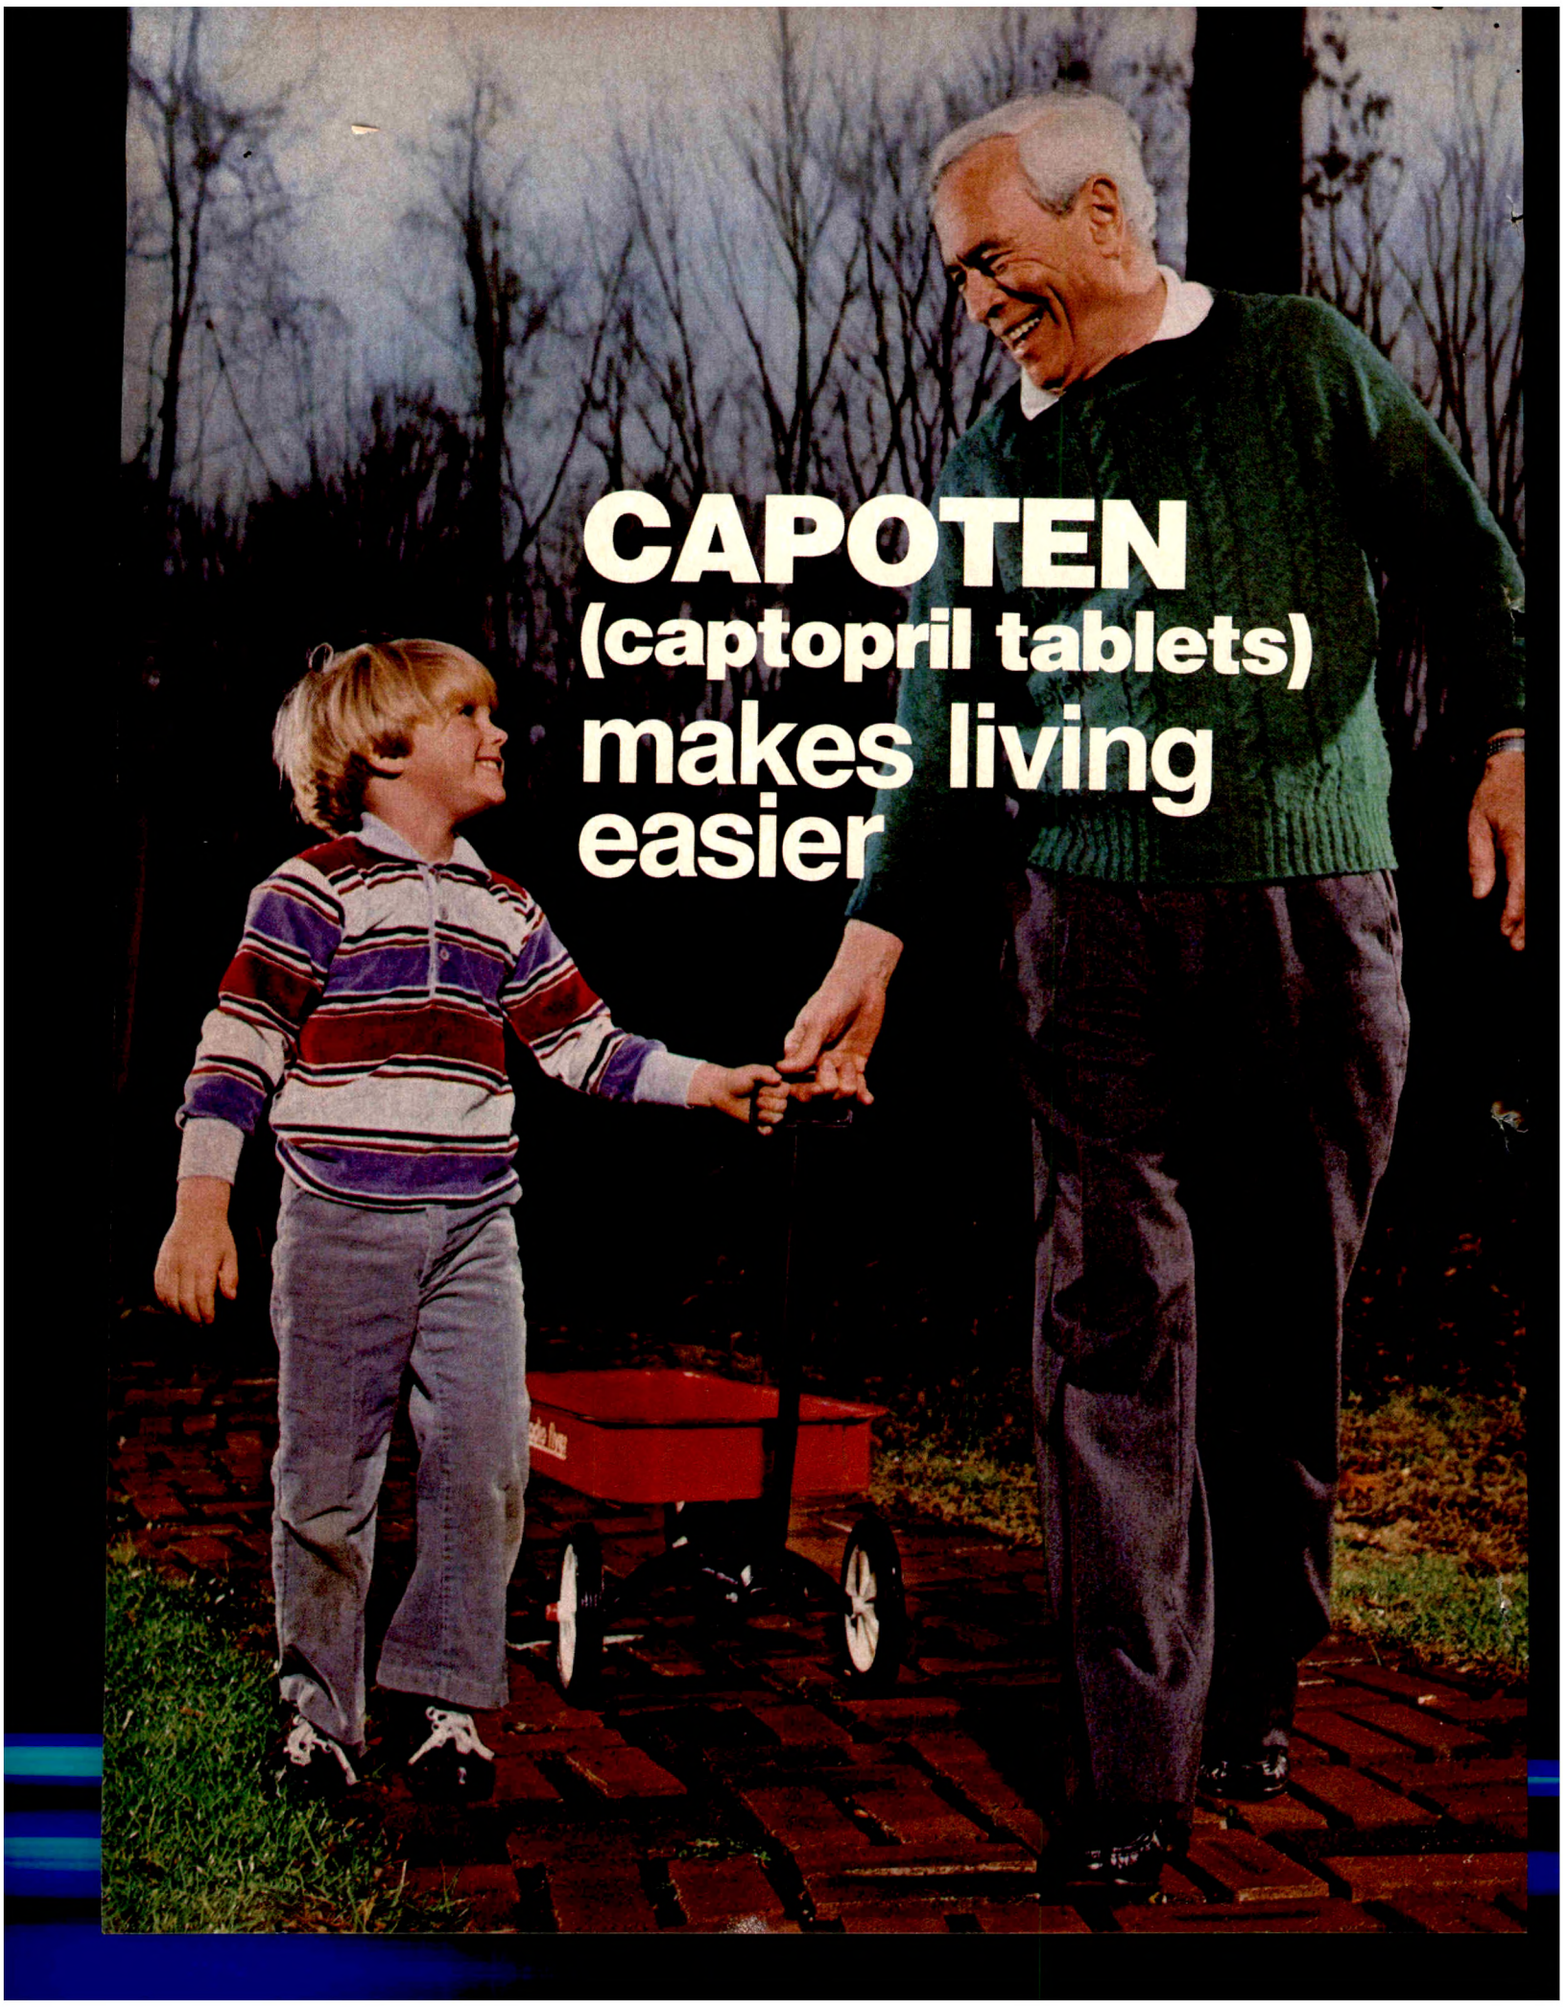
Heart failure makes
life more difficult



CAPOTEN
(captopril tablets)
makes living
easier

SQUIBB

ACE* INHIBITOR

CAPOTEN®
(captopril tablets)

Can make the difference between merely existing and actively living

With the availability of CAPOTEN, heart failure† patients can enjoy an enhanced quality of life. Because, in patients who require more than digitalis and diuretics, CAPOTEN can improve their hemodynamic profile[1] and provide an opportunity to feel better.

- Eases principal heart failure symptoms[1]
- Restores patients' sense of well-being[1]
- Increases patients' capacity for exercise[1], allowing them to participate more fully in the physical activities of everyday life

†CAPOTEN is indicated in patients with heart failure who have not responded adequately to or cannot be controlled by conventional diuretic and digitalis therapy. CAPOTEN is to be used with diuretics and digitalis.

*Angiotensin Converting Enzyme

Please see brief summary of prescribing information on last pages of this advertisement.

CAPOTEN
Your First Choice After Digitalis and Diuretics

ACE*INHIBITOR

CAPOTEN®
(captopril tablets)

CAPOTEN has been associated with the development of neutropenia/agranulocytosis (0.3% of 4,000 patients) or proteinuria (1.2% of 4,000 patients).† These serious side effects are more likely to occur in patients with predisposing conditions, such as renal impairment or autoimmune disease, or in patients receiving therapy known to suppress the autoimmune response.

The following precautionary guidelines are recommended for all patients receiving CAPOTEN:

- **Obtain urinary protein level estimates prior to initiating therapy, at monthly intervals for the first nine months of treatment, and periodically thereafter.**
- **Obtain WBC counts at the initiation of therapy, at two-week intervals for the first three months of treatment, and periodically thereafter.**
- **Carefully review the WARNINGS and ADVERSE REACTIONS sections in the complete prescribing information, with particular attention to the patient at increased risk.**
- **The most frequently occurring adverse reactions are skin rash and taste alteration; both effects are generally mild, reversible, or self-limited.**

*Angiotensin Converting Enzyme

†Please see brief summary of prescribing information on last pages of this advertisement for INDICATIONS AND USAGE, WARNINGS, and ADVERSE REACTIONS.

Reference: 1. Data on file, Squibb Institute for Medical Research.

CAPOTEN® TABLETS
Captopril Tablets

INDICATIONS: Hypertension — Because serious adverse effects have been reported (see WARNINGS), CAPOTEN is indicated for treatment of hypertensive patients who on multidrug regimens have either failed to respond satisfactorily or developed unacceptable side effects.
Heart Failure: CAPOTEN (captopril) is indicated in patients with heart failure who have not responded adequately to or cannot be controlled by conventional diuretic and digitalis therapy. CAPOTEN is to be used with diuretics and digitalis.
WARNINGS: Proteinuria — Total urinary proteins >1 g/day were seen in 1.2% of patients on captopril; the nephrotic syndrome occurred in about ¼th of these cases. About 60% of affected patients had evidence of prior renal disease; the remainder had no known renal dysfunction. In most cases, proteinuria subsided or cleared within 6 months whether or not captopril was continued. The BUN and creatinine were seldom altered in proteinuric patients.

Membranous glomerulopathy was found in nearly all the proteinuric patients on captopril who were biopsied and may be drug related. Most cases of proteinuria occurred by the 8th month of therapy. Patients should have urinary protein estimates (dip-stick on 1st morning urine, or quantitative 24-hr urine — the latter provides greater precision when proteinuria is persistent and/or at low levels) before therapy, at approx. monthly intervals for the 1st 9 months of therapy, and periodically thereafter. For patients who develop proteinuria >1 g/day, or increasing proteinuria, the benefits and risks of continuing captopril should be evaluated.

Neutropenia/Agranulocytosis — Neutropenia (<300/mm³) associated with myeloid hypoplasia (probably drug related) occurred in about 0.3% of captopril treated patients. About half of the neutropenic patients developed systemic or oral cavity infections or other features of agranulocytosis. Most of the neutropenic patients had severe hypertension and renal function impairment; about half had systemic lupus erythematosus (SLE), or another autoimmune/collagen disorder; multiple concomitant drug therapy was common, including immunosuppressive therapy in a few cases. Daily doses of captopril in the leukopenic patients were relatively high, particularly in view of their diminished renal function. The neutropenia appeared 3 to 12 weeks after starting captopril; it developed relatively slowly, taking 10 to 30 days to have white blood count fall to its nadir; neutrophils returned to normal in about 2 weeks (other than 2 patients who died of sepsis).

Use captopril with caution in patients with impaired renal function, serious autoimmune disease (particularly SLE), or who are exposed to other drugs known to affect the white cells or immune response. In patients at particular risk (as noted above), perform white blood cell and differential counts prior to therapy, at about 2-week intervals for about the 1st 3 months of therapy, and periodically thereafter.

The risk of neutropenia in patients who are less seriously ill or who receive lower dosages appears to be smaller. In these patients white blood cell counts should be performed every 2 weeks for the 1st 3 months of therapy, and periodically thereafter. Perform differential counts when leukocytes are <4000/mm³ or the pretherapy white count is halved. All patients treated with captopril should be told to report any signs of infection (e.g., sore throat; fever); if infection is suspected, perform counts without delay. Since discontinuation of captopril and other drugs has generally led to prompt return of the white count to normal, upon confirmation of neutropenia (neutrophil count <1000/mm³) withdraw captopril and closely follow the patient's course.
Hypotension — Excessive hypotension was rarely seen in hypertensive patients but is a possibility in severely salt/volume-depleted persons such as those treated vigorously with diuretics (see PRECAUTIONS [Drug Interactions]).

In heart failure, where blood pressure was either normal or low, transient decreases in blood pressure >20% were recorded in about ½ the patients. This transient hypotension may occur after any of the first several doses and is usually well tolerated, although rarely it has been associated with arrhythmia or conduction defects. A starting dose of 6.25 or 12.5 mg tid may minimize the hypotensive effect. Patients should be followed closely for the first 2 weeks of treatment and whenever the dose of captopril and/or diuretic is increased.

BECAUSE OF THE POTENTIAL FALL IN BLOOD PRESSURE IN THESE PATIENTS, THERAPY SHOULD BE STARTED UNDER VERY CLOSE MEDICAL SUPERVISION.
PRECAUTION: General: *Impaired Renal Function,* Hypertension — Some hypertensive patients with renal disease, particularly those with severe renal artery stenosis, have developed increases in BUN and serum creatinine. It may be necessary to reduce captopril dosage and/or discontinue diuretic. For some of these patients, normalization of blood pressure and maintenance of adequate renal perfusion may not be possible. Heart Failure — About 20% of patients develop stable elevations of BUN and serum creatinine >20% above normal or baseline upon long-term treatment. Less than 5% of patients, generally with severe preexisting renal disease, required discontinuation due to progressively increasing creatinine. See DOSAGE AND ADMINISTRATION, ADVERSE REACTIONS [Altered Laboratory Findings]. *Valvular Stenosis* — A theoretical concern, for risk of decreased coronary perfusion, has been noted regarding vasodilator treatment in patients with aortic stenosis, due to decreased afterload reduction.
Surgery/Anesthesia — If hypotension occurs during major surgery or anesthesia, and is considered due to the effects of captopril, it is correctable by volume expansion.
Drug Interactions: *Hypotension: Patients on Diuretic Therapy* — Precipitous reduction of blood pressure may occasionally occur within the 1st 3 hours after administration of the initial captopril dose in patients on diuretics, especially those recently placed on diuretics and those on severe dietary salt restriction or dialysis. This possibility can be minimized by either discontinuing the diuretic or increasing the salt intake about 1 week prior to initiation of captopril therapy. Alternatively, provide medical supervision for at least 3 hours after the initial dose in hypertensive patients.
Agents Having Vasodilator Activity: In heart failure patients vasodilators should be administered with caution.
Agents Causing Renin Release — Captopril's effect will be augmented by

 (Continued on next page.)

(continued from preceding page)

antihypertensive agents that cause renin release.

Agents Affecting Sympathetic Activity — The sympathetic nervous system may be especially important in supporting blood pressure in patients receiving captopril alone or with diuretics. Beta-adrenergic blocking drugs add some further antihypertensive effect to captopril, but the overall response is less than additive. Therefore, use agents affecting sympathetic activity (e.g., ganglionic blocking agents or adrenergic neuron blocking agents) with caution.

Agents Increasing Serum Potassium — Give potassium-sparing diuretics or potassium supplements only for documented hypokalemia, and then with caution, since they may lead to a significant increase of serum potassium.

Drug/Laboratory Test Interaction: Captopril may cause a false-positive urine test for acetone.

Carcinogenesis, Mutagenesis, and Impairment of Fertility: Two-year studies with doses of 50 to 1350 mg/kg/day in mice and rats failed to show any evidence of carcinogenic potential. Studies in rats have revealed no impairment of fertility.

Usage in Pregnancy: There are no adequate and well-controlled studies in pregnant women. Embryocidal effects were observed in rabbits. Therefore, captopril should be used during pregnancy only if the potential benefit outweighs the potential risk to the fetus.

Nursing Mothers: Captopril is secreted in human milk. Exercise caution when administering captopril to a nursing woman, and, in general, nursing should be interrupted.

Pediatric Use: Safety and effectiveness in children have not been established although there is limited experience with use of captopril in children from 2 months to 15 years of age. Dosage, on a weight basis, was comparable to that used in adults. Captopril should be used in children only if other measures for controlling blood pressure have not been effective.

ADVERSE REACTIONS: Reported incidences are based on clinical trials involving about 4000 patients.

Renal — One to 2 of 100 patients developed proteinuria (see WARNINGS). Renal insufficiency, renal failure, polyuria, oliguria, and urinary frequency in 1 to 2 of 1000 patients.

Hematologic — Neutropenia/agranulocytosis occurred in about 0.3% of captopril treated patients (see WARNINGS). Two of these patients developed sepsis and died.

Dermatologic — Rash (usually mild, maculopapular, rarely urticarial), often with pruritus and sometimes with fever and eosinophilia, in about 10 of 100 patients, usually during the 1st 4 weeks of therapy. Pruritus, without rash, in about 2 of 100 patients. A reversible associated pemphigoid-like lesion, and photosensitivity have also been reported. Angioedema of the face, mucous membranes of the mouth, or of the extremities in about 1 of 100 patients — reversible on discontinuance of captopril therapy. One case of laryngeal edema reported. Flushing or pallor in 2 to 5 of 1000 patients.

Cardiovascular — Hypotension in about 2 of 100 patients. See WARNINGS (Hypotension) and PRECAUTIONS (Drug Interactions) for discussion of hypotension on initiation of captopril therapy. Tachycardia, chest pain, and palpitations each in about 1 of 100 patients. Angina pectoris, myocardial infarction, Raynaud's syndrome, and congestive heart failure each in 2 to 3 of 1000 patients.

Dysgeusia — About 7 of 100 patients developed a diminution or loss of taste perception; taste impairment is reversible and usually self-limited even with continued drug use (2 to 3 months). Gastric irritation, abdominal pain, nausea, vomiting, diarrhea, anorexia, constipation, aphthous ulcers, peptic ulcer, dizziness, headache, malaise, fatigue, insomnia, dry mouth, dyspnea, and paresthesias reported in about 0.5 to 2% of patients but did not appear at increased frequency compared to placebo or other treatments used in controlled trials.

Altered Laboratory Findings: Elevations of liver enzymes in a few patients although no causal relationship has been established. Rarely cholestatic jaundice and hepatocellular injury with secondary cholestasis have been reported. A transient elevation of BUN and serum creatinine may occur, especially in volume-depleted or renovascular hypertensive patients. In instances of rapid reduction of longstanding or severely elevated blood pressure, the glomerular filtration rate may decrease transiently, also resulting in transient rises in serum creatinine and BUN. Small increases in serum potassium concentration frequently occur, especially in patients with renal impairment (see PRECAUTIONS).

OVERDOSAGE: Primary concern in correction of hypotension. Volume expansion with an I.V. infusion of normal saline is the treatment of choice for restoration of blood pressure. Captopril may be removed from the general circulation by hemodialysis.

DOSAGE AND ADMINISTRATION: CAPOTEN should be taken one hour before meals. Dosage must be individualized; see DOSAGE AND ADMINISTRATION section of package insert for detailed information regarding dosage in hypertension and in heart failure. Because CAPOTEN (captopril) is excreted primarily by the kidneys, dosage adjustments are recommended for patients with impaired renal function.

Consult package insert before prescribing CAPOTEN (captopril).

HOW SUPPLIED: Available in tablets of 25, 50, and 100 mg in bottles of 100, and in UNIMATIC® unit-dose packs of 100 tablets.

SQUIBB

INNOVATORS IN CARDIOVASCULAR MEDICINE

Princeton, NJ 08540 524-521 Issued: September 1984

CLASSIFIED

SEATTLE—CARDIOLOGIST for large prepaid health care organization with 420 medical staff in Puget Sound region. Have vacancy in 7 member department. Laboratory experience and expertise required. Send CV and inquiries to Bruce Pearson, Group Health Cooperative, 300 Elliott Ave. W., Seattle, WA 98119.

HOUSTON—POSITION AVAILABLE FOR BOARD CERTIFIED OR ELIGIBLE INVASIVE CARDIOLOGIST. Accredited 68-physician internal medicine group. For further information, send Curriculum Vitae to Administrator, Diagnostic Clinic of Houston, 6448 Fannin, Houston, Texas 77030.

CARDIOLOGIST: Ohio, BC/BE, with training in invasive and noninvasive procedures, M.D. degree must be from a U.S. medical school. Attractive salary. Please send curriculum vitae and references to: P.O. Box 290, The American Journal of Cardiology, 875 Third Ave., New York, N.Y. 10022.

CARDIOLOGIST—Board certified or eligible. Position available for cardiologist in midwestern, 500 bed, university affiliated hospital. 40 approved Internal Medicine residency positions. Geographic full-time to include primarily teaching and administration. Practice an option. Available immediately. Send curriculum vitae to Box 335, The American Journal of Cardiology, 875 Third Ave., New York, N. Y. 10022.

CARDIOLOGIST

BC/BE, non-invasive or invasive, to join large cardiology group. Midwest metropolitan setting. Send CV to Box 365, American Journal of Cardiology, 875 Third Avenue, New York, New York 10022.

PERFORMANCE STRESS

SYSTEM Q™ BY QUINTON

There are times when only the best will do: When you want to stress test *your* way—without compromise. When doctors share a stress system. When you need flexibility to perform different procedures.

That's when you need the high performance capabilities of SYSTEM Q by Quinton—the most advanced stress test system ever created.

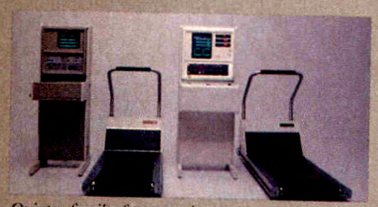
Ultimate flexibility.

No other system gives you more control over a stress test. You program the recorder, screen displays, treadmill and even the ECG analysis to meet your specific requirements.

And your colleagues can do the same. SYSTEM Q can store up to four programmed test procedures, each customized to meet the needs of a different physician. (Or a different test.) It's the closest you'll come to a separate system to meet the needs of every doctor.

Superior diagnostic information.

SYSTEM Q gives you more data, more accurately than ever before possible: An averaged beat final report, with computed ST parameters. The most sophisticated QRS detection algorithms ever developed. A more precise calculation of ST parameters. A more stable heartrate indication. And more.



Quinton family of stress testing equipment

When you need high powered capabilities, get the high performance stress test system: SYSTEM Q by Quinton. (It performs well on the bottom line, too.) For more information about the Quinton family of stress testing equipment, call or write us at 2121 Terry Ave., Seattle, WA 98121. 1-800-426-0347. Telex 328840.

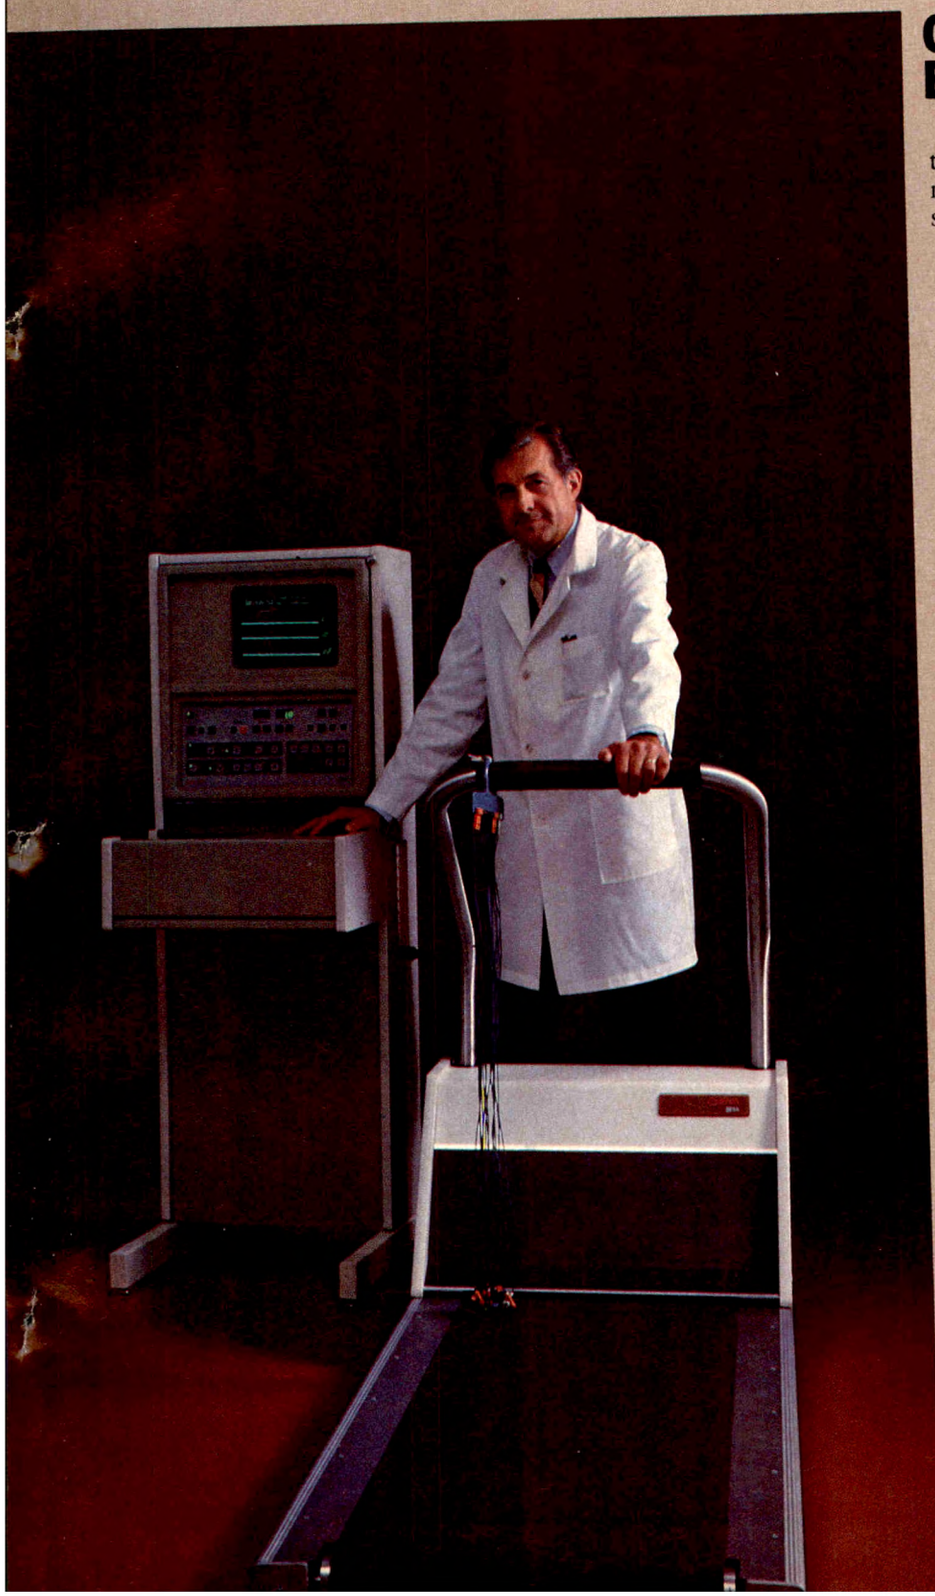
ECONOMIC STRESS



Q-STRESS™ BY QUINTON

How can you afford to stress test in the office? When you consider the economics of Quinton's new Q-STRESS system, how can you afford not to?

Priced to be affordable.

For about the cost of an ECG cart and a treadmill, Q-STRESS gives you a dedicated, state-of-the-art stress test system (including treadmill).

More important, it gives you capabilities you'd expect only on a hospital system. That's because it's based on the same forward technology that's made Quinton's SYSTEM Q the gold standard for hospitals and clinics.

Engineered to perform.

Just look at the quantity and quality of information Q-STRESS gives you: Three full channels of ECG, with split freeze capability. Heart rate and stage time. ST level and slope. Even a comprehensive final report.

And nothing matches the quality o our new thermal print-head recorder. Crisp. And clear. With absolutely no fading on the R-wave.

What's more, it's simple to use. Easy to maintain. With self-testing fo reliability.

Quinton family of stress testing equipment

Discover the economic advantages o stress testing in your office. For more information on Q-STRESS or the Qu ton family of stress testing equipment, call or write us at 2121 Terry Ave., Seattle, WA 98121. 1-800-426-0347. Telex 328840.

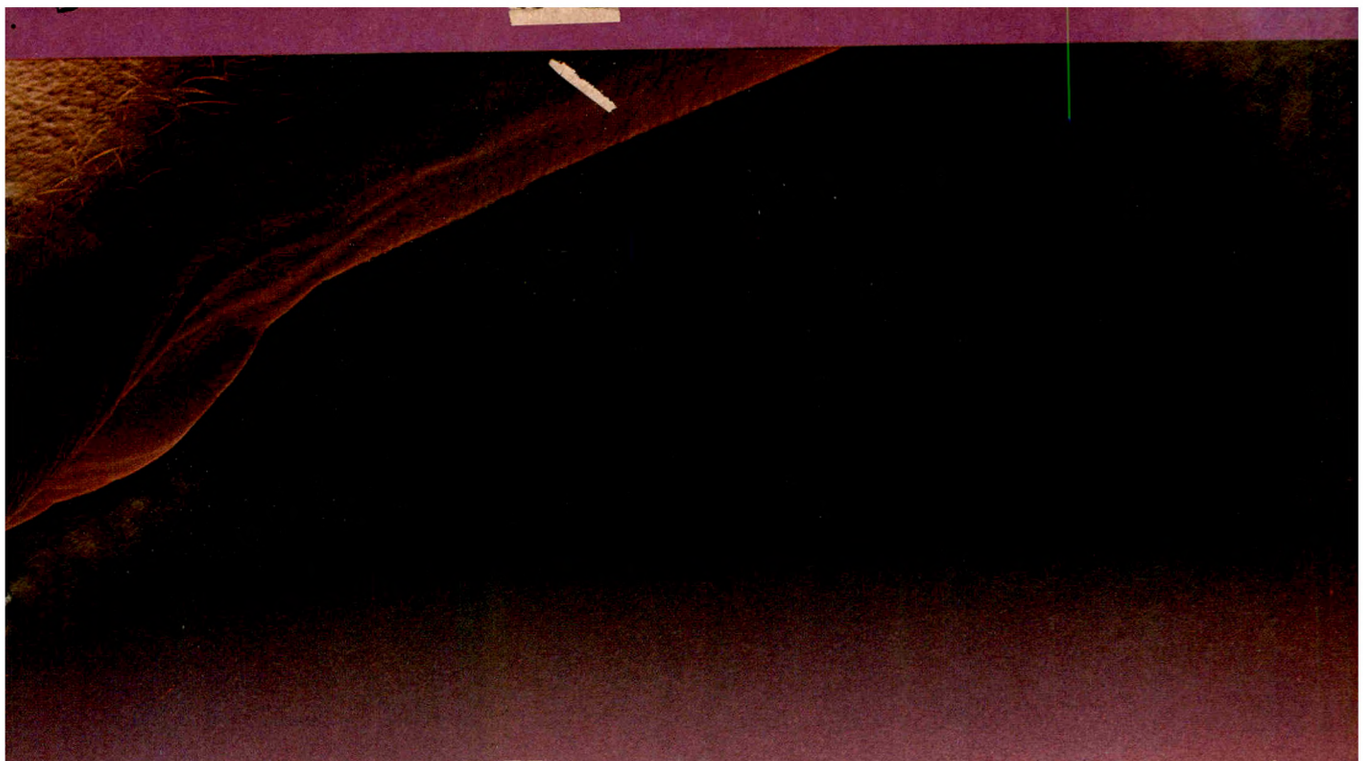
TRANSDERM-NITRO 5



Transderm-Nitro®

nitroglycerin 24-hr systems: 2.5 mg, 5 mg, 10 mg, 15 mg

CIBA

Stays on better

Reformulated adhesive delivers optimum staying power. Results of two studies* with both placebo and active systems on normal subjects proved that Transderm-Nitro has an almost 100% adhesion rate, even under the most adverse conditions, including hot, humid summer weather.

Handles better

Clear plastic 3M backing is easy to remove—practically slides right off. There's no risk of your patient damaging the system. Especially easy to handle for elderly patients.

Comes off without significant irritation

The reformulated adhesive is strong, yet gentle on the skin. The studies* also showed no significant irritation after removal.

Contraindicated in patients with intolerance to organic nitrate drugs.

All transdermal nitroglycerin products are being marketed pending final evaluation of effectiveness by the FDA. (See Brief Summary of Prescribing Information on the next page.)

Transderm®-Nitro

(nitroglycerin)
Transdermal Therapeutic System

BRIEF SUMMARY *(FOR FULL PRESCRIBING INFORMATION, SEE PACKAGE INSERT)*

INDICATIONS AND USAGE
This drug product has been conditionally approved by the FDA for the prevention and treatment of angina pectoris due to coronary artery disease. The conditional approval reflects a determination that the drug may be marketed while further investigation of its effectiveness is undertaken. A final evaluation of the effectiveness of the product will be announced by the FDA.

CONTRAINDICATIONS
Intolerance of organic nitrate drugs, marked anemia, increased intraocular pressure or increased intracranial pressure.

WARNINGS
In patients with acute myocardial infarction or congestive heart failure, Transderm-Nitro system should be used under careful clinical and/or hemodynamic monitoring.

In terminating treatment of anginal patients, both the dosage and frequency of application must be gradually reduced over a period of 4 to 6 weeks to prevent sudden withdrawal reactions, which are characteristic of all vasodilators in the nitroglycerin class.

Transdermal nitroglycerin systems should be removed before attempting defibrillation or cardioversion because of the potential for altered electrical conductivity which may enhance the possibility of arcing, a phenomenon associated with the use of defibrillators.

PRECAUTIONS
Symptoms of hypotension, such as faintness, weakness or dizziness, particularly orthostatic hypotension may be due to overdosage. When these symptoms occur, the dosage should be reduced or use of the product discontinued.

Transderm-Nitro system is not intended for immediate relief of anginal attacks. For this purpose occasional use of the sublingual preparations may be necessary.

ADVERSE REACTIONS
Transient headaches are the most common side effect, especially when higher doses of the drug are used. These headaches should be treated with mild analgesics while Transderm-Nitro therapy is continued. When such headaches are unresponsive to treatment, the nitroglycerin dosage should be reduced or use of the product discontinued.

Adverse reactions reported less frequently include hypotension, increased heart rate, faintness, flushing, dizziness, nausea, vomiting, and dermatitis. These symptoms are attributable to the known pharmacologic effects of nitroglycerin, but may be symptoms of overdosage. When they persist the dose should be reduced or use of the product discontinued.

DOSAGE AND ADMINISTRATION
Therapy should be initiated with application of one Transderm-Nitro 5 system to the desired area of skin. Many patients prefer the chest; if hair is likely to interfere with system adhesion or removal, it can be clipped prior to placement of the system. Each system is designed to remain in place for 24 hours, and each successive application should be to a different skin area. Transderm-Nitro system should not be applied to the distal parts of the extremities.

The usual dosage is one Transderm-Nitro 5 system every 24 hours. Some patients, however, may require the Transderm-Nitro 10 system. If a single Transderm-Nitro 5 system fails to provide adequate clinical response, the patient should be instructed to remove it and apply either two Transderm-Nitro 5 systems or one Transderm-Nitro 10 system. More systems may be added as indicated by continued careful monitoring of clinical response. The Transderm-Nitro 2.5 system is useful principally for decreasing the dosage gradually, though it may provide adequate therapy for some patients when used alone.

The optimal dosage should be selected based upon the clinical response, side effects, and the effects of therapy upon blood pressure. The greatest attainable decrease in resting blood pressure that is not associated with clinical symptoms of hypotension especially during orthostasis indicates the optimal dosage. To decrease adverse reactions, the size and/or number of systems should be tailored to the individual patient's needs.

Do not store above 86°F (30°C).

PATIENT INSTRUCTIONS FOR APPLICATIONS
A patient leaflet is supplied with the systems.

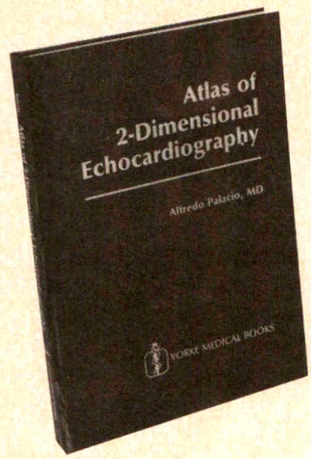
A "how-to-do-it" text/atlas presenting the broadest range of normal and abnormal 2-dimensional echocardiograms



Atlas of 2-Dimensional Echocardiography

by Alfredo Palacio, MD
Director of National Institute of Cardiology, Guayaquil, Ecuador

Foreword by David H. Spodick, MD, DSc
Professor of Medicine, University of Massachusetts Medical School; Director, Division of Cardiology, St. Vincent Hospital, Worcester, Massachusetts

ISBN 0-914316-35,4, 198pp., illus., large format
8¼ x 12, March '83, $69.00

2-dimensional echocardiography complemented by M-mode echocardiography has become one of the most common noninvasive diagnostic tools used by the cardiologist. With publication of the ATLAS of 2-DIMENSIONAL ECHOCARDIOGRAPHY, neophyte and expert alike now have available to them the most truly usable didactic presentation of the subject ever published.

A true atlas, this book provides in a **large 8½ x 12 format 251 black and white half tones, 152 line drawings and 6 charts** which illustrate in exacting detail how to perform and interpret 2-dimensional echocardiograms on patients with existing and/or suspected heart disease. The lucid accompanying text leads the reader step-by-step through the entire process, leaving little to the imagination. It presents in the most simple, direct way possible the broadest range of normal and abnormal 2-dimensional echocardiograms. The descriptions and detailed illustrations in its technical sections will ensure the superior level of performance of echocardiographic techniques that is a sine qua non for good results.

Serial Measurements of Systolic Time Intervals During Treatment with Hydrochlorothiazide Alone and Combined with Other Antihypertensive Agents

MARY C. KYLE, MS, and EDWARD D. FREIS, MD

As part of the Veterans Administration cooperative studies on antihypertensive agents, systolic time intervals (STIs) were recorded before and after 2 or 4 weeks of treatment with hydrochlorothiazide (HCTZ) alone in 320 asymptomatic patients with mild to moderate hypertension. After treatment with HCTZ, left ventricular ejection time corrected for heart rate (ΔLVET) was significantly reduced. This decrease is consistent with other hemodynamic observations indicating a reduced preload and stroke volume after administration of thiazides. Electromechanical systole corrected for heart rate (ΔQS_2) decreased, while the ratio of preejection period to LVET (PEP/LVET) increased, reflecting reduced left ventricular function. PEP did not change. Four step 2 drugs—hydralazine, prazosin, oxprenolol and propranolol—were then added randomly to HCTZ and further recordings of STIs were taken at 1 and 6 months after administration of these drugs. The ΔLVET and ΔQS_2 increased and PEP/LVET decreased, suggesting improved left ventricular function after administration of all 4 agents. These changes may have been due to the added agents or to the recovery of cardiac output that occurs independently during long-term treatment with thiazide diuretic drugs alone. PEP decreased slightly after hydralazine and prazosin and increased slightly after treatment with the β-blocking drugs, although none of these changes were significant except those during hydralazine treatment. Processing of the STIs was greatly facilitated by the automated system for recording and analyzing the measurements.

(Am J Cardiol 1985;55:107–111)

Changes in systolic time intervals (STI) have been reported with a variety of cardiovascular agents.[1] Most of these studies have explored the effects of single doses and few have been concerned with the effects of long-term administration of cardiovascular agents on STI. Some drugs with important effects on the cardiovascular system, such as the thiazide diuretic drugs, have been little studied with STI. The present study presents the effects of hydrochlorothiazide (HCTZ) on left ventricular performance in hypertensive patients as determined by STI.

Methods

The subjects were male hypertensive patients enrolled in 2 Veterans Administration Cooperative Studies.[2,3] Both studies evaluated various step 2 antihypertensive agents in patients whose diastolic blood pressures (BP) were not reduced to below 90 mm Hg with HCTZ alone. In the study in which hydralazine (30 to 150 mg/day) or prazosin (3 to 15 mg/day) were added, the period of treatment with HCTZ alone (75 mg/day) was 2 weeks.[2] In the study with oxprenolol or propranolol (120 to 360 mg/day), it was 4 weeks.[3] HCTZ and the step 2 agents were administered in divided doses 3 times daily.

The range of sitting diastolic BP required for admission to both studies was 95 to 114 mm Hg as the average of the last 2 biweekly visits during a 4- to 8-week pretreatment placebo period.[2,3] Patients with severe complications of hypertension and noncompliant patients (determined by placebo pill counts) were excluded.

There were no significant differences in the characteristics of the 2 groups of patients. The average age was 51 years and exclusion criteria were essentially the same in both studies. The racial distribution, blood chemistry levels and heart rate also were comparable in the 2 groups. Because of the similar characteristics, it was considered valid to compare the results of the 2 studies with respect to the effects of HCTZ per se.

In the hydralazine-prazosin study, 163 patients had satisfactory recordings of STIs before and after 2 weeks of treat-

PEP/LVET	0.40 ± 0	+0.03 ± 0†	0.39 ± 0	+0.03 ± 0†

* Values are mean ± standard error of the mean.
† $p \leq 0.001$; ‡ $p \leq 0.01$.
BP = blood pressure; HCTZ = hydrochlorothiazide; ΔLVET = left ventricular ejection time corrected for heart rate; PEP = preejection period; ΔQS_2 = electromechanical systole corrected for heart rate.

ment with HCTZ alone and in the oxprenolol-propranolol study, 157 patients had satisfactory recordings after 4 weeks of treatment with HCTZ alone. After the recordings were obtained, patients were then randomly assigned double-blind to 1 of the step 2 drugs and further recordings of STI were taken 1 and 6 months after randomization.

The STI were determined from simultaneous tape recordings of the electrocardiogram, phonocardiogram and the external carotid pulse wave taken in the supine position.[4] The recordings were taken at approximately the same time of day to avoid diurnal variations.[1] Blood pressure readings were taken in the right arm by means of a standard sphygmomanometer 3 times in the sitting position and the average was recorded.

The computer program for measuring STI[5,6] uses digitized data and pattern recognition algorithms to identify the salient points in the electrocardiogram, phonocardiogram and carotid pulse wave. When tested in 142 subjects, it showed close agreement with visual measurements.[5] The program for measuring STI has been incorporated into a self-contained and mobile, microcomputer-based, portable system[6] that provides immediate readout not only of STI, but also an analysis of the electrocardiogram.[7] This system displays the STI waveforms with markers where the computer identified the important landmarks and then presents a complete report containing the various STI indexes and demographic information.

Values for left ventricular ejection time (LVET) and electromechanical systole (QS_2) were corrected for heart rate and were expressed as ΔQS_2 and ΔLVET, which represent the differences between the observed values and those predicted from the regression equation relating QS_2 or LVET and heart rate as derived from a previous series of 199 normal male subjects.[4] Preejection period (PEP) and PEP/LVET were not corrected because of the small correlation observed between PEP and heart rate and because of evidence from acute studies indicating that PEP should not be adjusted for heart rate.[4]

Results

Hydrochlorothiazide alone: The average decrease in diastolic BP with HCTZ alone was 5 mm Hg in the 2-week trial and 4 mm Hg in the 4-week trial. After 2 and 4 weeks of treatment with HCTZ, mean heart rate increased 3 and 2 beats/min, respectively. All of these changes were significant (Table I). There was also a significant decrease in ΔLVET averaging 16 and 14 ms, respectively, in the 2- and 4-week studies ($p < 0.001$). PEP remained essentially unchanged. ΔQS_2 also decreased while the ratio PEP/LVET increased significantly. The reductions in ΔLVET and ΔQS_2 were slightly greater at 2 weeks than at 4 weeks after beginning treatment, although the difference was significant only with respect to ΔQS_2 ($p < 0.05$).

Addition of hydralazine: Compared with the levels of diastolic BP attained with HCTZ alone, a further reduction, averaging 7 mm Hg at 1 month and 8 mm Hg at 6 months, was achieved after the addition of hydralazine (Table II). Average heart rate was essentially unchanged.

The decrease in ΔLVET that occurred after therapy with HCTZ alone was partially reversed after the addition of hydralazine. The increase from HCTZ alone was 11 ms at 6 months, which was greater than the 4-ms increase at 1 month. The change at 6 months was 5 ms short of complete return to pretreatment levels. PEP decreased 4 ms from the HCTZ level at both 1 and 6 months. Due to the compensating changes in ΔLVET and PEP, ΔQS_2 remained unchanged at 1 month but increased at 6 months, reflecting the greater increase in ΔLVET at that time. PEP/LVET decreased significantly, returning approximately to baseline values.

Addition of prazosin: The decrease in diastolic BP with the addition of prazosin was the same as that with hydralazine (Table II). Heart rate decreased slightly. The ΔLVET increased, paralleling the changes seen in the hydralazine group. The return toward pretreatment levels was significantly greater at 6 months than at 1 month after the addition of prazosin ($p < 0.01$). As a result, ΔQS_2 at the 6-month recording also increased significantly from the level with HCTZ alone. PEP decreased slightly, but the changes were not significant. PEP/LVET also decreased significantly.

Addition of propranolol: Compared with the effect of HCTZ alone, the reduction of diastolic BP after therapy with propranolol was slightly greater than that with the other drugs, averaging 9 mm Hg at 1 month and 11 mm Hg at 6 months (Table III). Heart rate decreased 11 beats/min. As with hydralazine and prazosin, ΔLVET increased significantly, the increase again being slightly greater at 6 months than at 1 month. As was also noted during therapy with the other agents, the recovery to pretreatment levels was not complete. The ΔQS_2 also increased significantly, reflecting the change in ΔLVET. PEP increased slightly but not significantly. A significant reduction in PEP/LVET occurred, similar to the change observed with hydralazine and prazosin.

Addition of oxprenolol: Reductions in diastolic BP and heart rate were slightly less with oxprenolol than with propranolol (Table III). The ΔLVET again increased significantly and PEP increased slightly but not significantly. The ΔQS_2 increased significantly and PEP/LVET decreased.

Discussion

After diuretic treatment the major changes in left ventricular performance as judged by STI were a decrease in ΔLVET and ΔQS_2 and a concurrent increase

TABLE II Mean Changes in Systolic Time Intervals After Addition of Hydralazine or Prazosin to Hydrochlorothiazide*

Measurement	HCTZ Plus Hydralazine (n = 80)			HCTZ Plus Prazosin (n = 70)

Abbreviations as in Table I.

in PEP/LVET, without a significant change in PEP. Gonzalez-Gomez et al[8] reported significant decreases in LVET and QS_2 corrected for heart rate, with no significant increase in corrected PEP. Ejection time may decrease because diuretic drugs reduce plasma and interstitial fluid volumes, resulting in a decrease in venous pressure, preload and cardiac output.[9,10] Other interventions that reduce preload, such as upright tilting and venous tourniquets, also decrease LVET.[11,12] According to Stafford et al,[12] the shortening of the ejection time during upright tilt is probably secondary to the decrease in preload and end-diastolic volume.

Despite similar changes in LVET, the effects of thiazide diuretic drugs differ from those produced by upright tilting or venous tourniquets in that PEP remained unchanged after the diuretic drug, but was prolonged during upright tilting.[12] This difference may be related to 2 factors: (1) The reduction in supine preload may not be as great after diuretic therapy as during orthostasis, and (2) diastolic BP increases with tilting, increasing PEP, and decreases with diuretic drugs, decreasing PEP. The combination of a shortened LVET without compensatory increase in PEP may occur during various drug interventions.[13]

Pretreatment levels of PEP/LVET for these hypertensive patients were significantly higher ($p < 0.001$) than our normal value of 0.345,[4] and increased further after HCTZ. Thus, these patients probably had decreased left ventricular global performance at baseline as reflected by PEP/LVET and it was further reduced after HCTZ. The ΔQS_2 decreased significantly after HCTZ, possibly reflecting increased adrenergic activity induced by the decrease in plasma volume.

The effects of adding hydralazine or prazosin on the STI were similar. Changes after oxprenolol also were similar to those after propranolol, except for a lesser decrease in heart rate after oxprenolol. To simplify the discussion, the results with hydralazine and prazosin are considered as a unit for comparison with the 2 β-blocking drugs.

Diastolic BP decreased similarly with both hydralazine-prazosin and oxprenolol. The decrease was somewhat greater with propranolol, particularly after 6 months. Heart rate decreased with the β-blocking drugs and remained unchanged with hydralazine-prazosin. An increase in ΔLVET from the depressed levels noted with HCTZ alone was noted with all 4 step 2 drugs. The effects of continuous treatment with hydralazine or prazosin alone on the STI is unknown. After propranolol was given to patients with coronary heart disease[14,15] or hypertension[8] and to normal subjects,[16] corrected LVET either did not change significantly or decreased. During long-term treatment with propranolol, ΔLVET remains unchanged from pretreatment levels.[4]

Left ventricular function improved over the long term with step 2 drugs. This was manifested principally by a decrease in PEP/LVET with all 4 of the step 2 regimens. However, the values did not go lower than those

observed during pretreatment. The ΔLVET increased from the moderately depressed levels during short-term treatment with HCTZ alone, probably reflecting a return in left ventricular stroke volume. The increase in ΔQS_2 is consistent with resetting of the adrenergic system during long-term treatment.

PEP decreased slightly after hydralazine-prazosin treatment and increased slightly after the β-adrenergic drug treatment. None of these changes were significant except those during hydralazine treatment. The changes, although minor, were in the expected direction. Hydralazine alone shortens PEP, reflecting its positive inotropic effect,[17] whereas propranolol alone prolongs PEP both acutely[1,16] and after long-term treatment[4] by inhibiting adrenergic stimulation. However, in the long-term study, propranolol plus HCTZ resulted in no change in PEP. This effect of added HCTZ may have been a result of the significantly lower diastolic BP with the combined drugs than with propranolol alone.[4] In the present study the addition of β-blocking drugs resulted in a slight, although insignificant increase in PEP as compared with thiazide alone, which may reflect the opposing influences of reduced adrenergic drive on the one hand and of additional reduction of diastolic BP on the other.

As previously indicated, thiazide diuretic drugs have widely different hemodynamic effects during short-term compared with long-term treatment. During short-term treatment reductions are found in plasma volume, total extracellular volume[9] and cardiac output while total peripheral resistance increases or remains unchanged.[10] These early changes appear to be the direct result of reduced preload. After long-term treatment, despite a continued reduction in volume,[9,18,19] cardiac output returns to normal and total peripheral resistance decreases.[20–22] The mechanism remains unclear for the time-dependent return to a more physiologic hemodynamic state despite continued volume reduction.[22]

In the present study, the changes in STI observed with thiazide alone probably reflect predominantly short-term responses, whereas the changes observed with combined therapy probably represent long-term effects of HCTZ. The improvement in left ventricular performance after the addition of all 4 step 2 drugs may have been caused by the effects of the added drugs, but it also may reflect the long-term response to diuretic drugs per se.

The present results indicate that measurements of STIs are a sensitive indicator of the cardiac effects of the thiazide diuretic drugs. The significant reductions in ΔLVET and ΔQS_2 and the increase in PEP/LVET are consistent with the known short-term hemodynamic effects of the thiazides. The long-term return of these indexes toward pretreatment levels, although possibly influenced by the addition of other drugs, also is consistent with the long-term hemodynamic effects of the diuretic agents.

STI measurements and analysis were greatly facilitated by the use of automated methods, which provided a rapid and accurate method for processing a large volume of records. The present study demonstrates that STIs provide a useful noninvasive method for identifying functional cardiac changes associated with antihypertensive drug treatment studies.

Enhanced 24-Hour Norepinephrine and Renin Secretion in Young Patients with Essential Hypertension: Relation with the Circadian Pattern of Arterial Blood Pressure

MICHAEL L. TUCK, MD, NAFTALI STERN, MD, and JAMES R. SOWERS, MD

This study examines the possibility that 24-hour differences in blood pressure (BP) regulation between hypertensive and normotensive subjects is related to changes in 24-hour secretory patterns in circulating pressor hormones. Nine young subjects with normal BP and 9 patients with essential hypertension (EH) were studied during 24-hour recumbency. Every 20 minutes samples were taken to determine plasma norepinephrine (NE) levels and plasma renin activity (PRA). BP was measured every 20 minutes by automatic recording. A distinct circadian rhythm was demonstrated for mean BP, NE and PRA in both groups. Nocturnal reductions in mean BP, NE and PRA related best to the sleep-wakefulness cycle in both groups. Circadian changes in mean BP correlated with NE levels in both normal subjects and patients with EH. The most striking difference between the 2 groups was the absolute levels of mean BP, NE and PRA, which were higher in the EH group at most time points in the 24-cycle. Differences in levels of NE and PRA between the 2 groups were most accentuated during sleep. Thus, young persons with EH show evidence of enhanced sympathetic nervous activity throughout the 24-hour cycle, which is most pronounced during sleep. The multiple sampling approach offers a more sensitive indicator of the role of pressor hormones in BP maintenance.

(Am J Cardiol 1985;55:112–115)

Plasma norepinephrine (NE) levels have been reported to be higher in persons with essential hypertension (EH), especially in younger persons, compared with age-matched controls.[1] Most studies used single time-point sampling, and given the considerable variability of plasma NE, only the inclusion of multiple investigations, as reported by Goldstein,[1] allow the analysis of plasma NE to reach significance in younger persons with EH. Using single time-point sampling, a large number of study subjects may be needed to compensate for the effect from factors known to influence NE secretion, such as body weight,[2] caloric intake[2] and dietary sodium.[3] Thus, it remains uncertain whether elevated NE derived by single time-point sampling can serve as an accurate indicator of sustained enhanced sympathetic tone in EH or, rather, reflects increased momentary stress responses. Repeated sampling for plasma NE levels after environmental habituation could provide a more reliable index of basal sympathetic tone. Further, if plasma NE is sampled frequently, coupled with multiple blood pressure (BP) measurements, the relevance of NE to the hour-to-hour control of basal BP can be assessed.

This study examines mean BP levels, plasma NE and plasma renin activity (PRA) sampled every 20 minutes for 24 hours in young persons with normal BP and those with EH. We examined whether maintenance of high BP in young subjects with EH was correlated with basal circulating levels of these pressor hormones as examined over a 24-hour period.

Methods

Subjects: Nine young patients (mean age 29 ± 3 years, range 22 to 46) with EH and 9 young, normotensive control subjects (mean age 24 ± 3 years, range 22 to 39) were studied after they gave informed consent. Patients with EH who were receiving treatment discontinued taking medication 3 weeks before the study. Secondary causes of high BP were excluded by history, physical examination, renal and electrolyte function, urinary metanephrine levels, and hypertensive urographic results. Subjects were hospitalized in a special study ward for 5 days and were studied while receiving a constant 100-mmol sodium and 80-mmol potassium diet with noncaffeinated fluids on request.

Twenty-four-hour recumbency studies: Before the study periods, subjects underwent 24 hours of habituation in a sound-proofed room containing a viewing window, with simulated blood sampling through an indwelling venous catheter and BP monitoring by an Arteriosonde (Hoffman-LaRoche) every 20 minutes. On the fifth day of the constant diet, 24-hour urine samples were collected to measure sodium and potassium levels. The 24-hour recumbency studies were performed on day 6, beginning at 0700 hours, when an indwelling venous catheter was inserted in an antecubital vein. Blood sampling was begun at 0800 hours. The venous catheter was connected to a sampling line passing through a port in the wall and maintained patent by a slow saline drip. Blood samples (2 ml) were collected every 20 minutes to measure NE and PRA levels. BP was monitored by Arteriosonde every 20 minutes. Mean BP was calculated as the diastolic plus one-third of the pulse pressure. Patients remained supine during the study except during meals, when the head of the bed was elevated 30°. The sleep period was 2300 to 0600 hours and meals were at 0800, 1200 and 1800 hours.

Hormone assays: PRA was collected in prechilled tubes and was measured by radioimmunoassay of the angiotensin I generated during 60 minutes of incubation at pH 7.4 and at 37°C.[4] The sensitivity of this assay is 0.2 ng/ml·hour^{-1} and the intraassay coefficient of variation is 5.9%. Samples for NE were collected in prechilled tubes, stored at −100°C and analyzed within 2 weeks. The plasma NE level was measured by the single isotope radioenzymatic method previously described.[3] The sensitivity of this assay is 10 pg/ml with an interassay coefficient of variation of 8 to 12%. Serum and urinary sodium levels were measured by atomic absorption spectrophotometry.

Differences in mean BP and hormonal assays at different times were analyzed using multiple-comparison analysis techniques and the repeated sampling analysis of variance method. Chronobiologic characteristics of mean BP and hormonal measurements during the 24-hour period were determined for each subject by previously described methods.[5]

Results

Patients with EH and control subjects did not differ significantly in mean urinary and sodium levels (122 ± 14 vs 111 ± 16 mmol per 24 hours) after 5 days of diet. They also had similar levels of urinary potassium for the constant potassium intake. Mean serum sodium levels (142 ± 2 mmol/liter) and serum potassium levels (4.2 ± 0.2 mmol/liter) in patients with EH were not significantly different from those in normotensive control subjects. Body weight and mean BP did not change significantly during the dietary equilibration period.

Mean blood pressure: Both groups of subjects demonstrated a reduction in mean BP that best related to the sleep-wakefulness cycle (Fig. 1). Mean BP levels were chosen for representation because they accurately reflected the circadian pattern of both systolic and diastolic blood pressure and correlated best with hormonal circadian patterns. The reduction in mean BP occurred during the first 2 hours of sleep and remained reduced until 30 to 90 minutes before the onset of arousal. The percent reduction in mean BP with sleep from previous waking levels was greater ($p < 0.05$) in the patients with EH (10.2%) than in the control subjects (8.2%). Mean BP increased abruptly in both groups in the early period before awakening and peak levels occurred during early morning. Thereafter, mean BP decreased toward the afternoon, with a moderate surge between 1700 and 2000 hours. The mean fluctuation of mean BP was 25 mm Hg (range 97 to 122) for patients with EH and 18 mm Hg (range 75 to 93) for the control subjects. The lowest mean BP levels in patients with EH occurred later in sleep than it did in the control subjects. Both groups had at least 5 to 6 mean BP peaks (mean BP 15% above mean 24-hour levels), which were most prominent during wakefulness. Absolute levels of mean BP were markedly higher in EH patients at all points during the 24-hour period. The transverse mean for mean BP levels for the patients with EH (110 ± 2.3 mm Hg) was greater ($p < 0.01$) than that for the normotensive control subjects (82 ± 4.7 mm Hg).

Norepinephrine: Reductions in NE during the 24-hour cycle best related to sleep periods, although

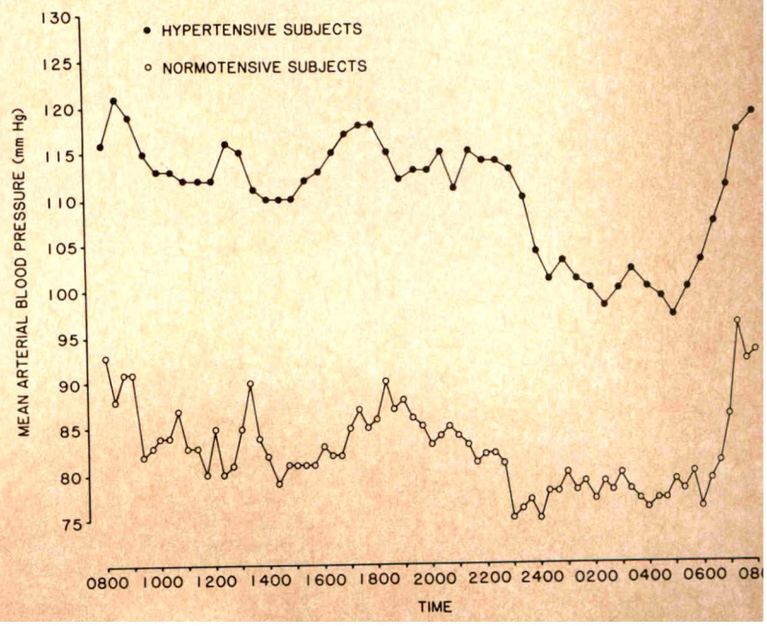

FIGURE 1. Mean values for recumbent levels of mean arterial blood pressure over a 24-hour period in normotensive control subjects and patients with essential hypertension. The sleep period was from 2300 to 0600 hours.

mean levels also slowly decreased throughout the waking hours in both groups (Fig. 2). In the normotensive control subjects there was a 33% reduction in levels between 0400 to 0600 hours, when values were reduced 58% from peak levels at 0920 hours. Arousal (0600 to 0700 hours) was accompanied by an abrupt 25 to 33% increase in NE in both groups. Individual analysis of NE curves in both groups revealed 5 to 6 secretory peaks (NE, 25% above the mean 24-hour concentration), usually occurring between 0600 and 1800 hours. Absolute levels of NE were significantly higher in patients with EH at most of the sampling times during the 24-hour period; the most marked difference occurred during the latter part of sleep (Fig. 2). The transverse mean NE in patients with EH (274 ± 5.9 pg/ml) was significantly ($p < 0.01$) greater than that in the control subjects (237 ± 6.6 pg/ml). Circadian changes in mean BP were highly correlated with plasma NE in the control subjects ($r = 0.62$; $p < 0.01$) and patients with EH ($r = 0.67$; $p < 0.01$).

Renin: PRA decreased in the early evening (1800 to 2300 hours) and began to slowly increase after 1 to 3 hours sleep, reaching the highest levels during the second half of sleep in both groups (Fig. 3). These changes were much less pronounced and consistent in the EH group compared with the control group. During the day there were no significant differences between PRA in either group. The number of secretory peaks for PRA (PRA, 25% above the mean 24-hour concentration) analyzed individually was 6 to 8 peaks for both groups. Although PRA was higher in EH subjects during the 24-hour period these differences reached statistical significance consistently only during sleep. The transverse mean PRA, however, was greater ($p < 0.05$) in the EH group (2.3 ± 0.6 ng/ml·hour^{-1}) than in the control group (1.3 ± 0.4 ng/ml·hour^{-1}). Correlations between 24-hour changes in PRA with NE and mean BP were not significant in either group.

Discussion

The results are consistent with previous reports that patients with EH, like normotensive persons, retain a distinct circadian rhythm of mean BP that best fits the sleep-wakefulness cycle.[6–8] However, mean BP values were significantly higher at all points in the 24-hour cycle in patients with EH. Thus, EH subjects, although they have a greater amplitude of mean BP, show a circadian rhythm of BP similar to that of normotensive

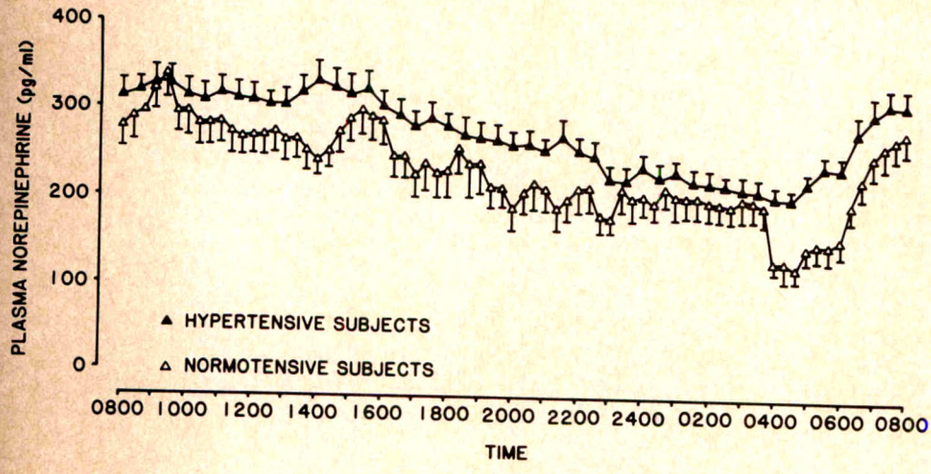

FIGURE 2. Plasma norepinephrine levels during recumbency over a 24-hour period in normotensive control subjects and patients with essential hypertension. Values are mean ± standard error of the mean.

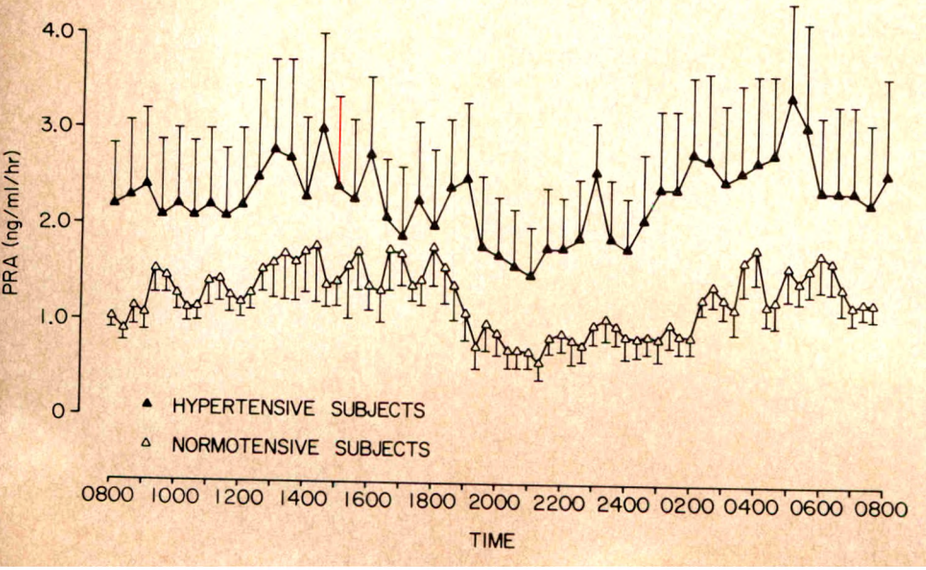

FIGURE 3. Levels of plasma renin activity (PRA) during recumbency over a 24-hour period in normotensive control subjects and patients with essential hypertension. Values are mean ± standard error of the mean.

persons. BP decreases during sleep in normal humans and also decreases in persons with EH, averaging 10 to 12% in both groups.[6–8] Home monitoring of BP in patients with EH shows an even greater sleep-related reduction in BP, and one cannot exclude some dampening effect on BP variation on admission of subjects to a metabolic study unit. A distinct absence of sleep-related reductions in BP was noted in malignant hypertension[8] and pheochromocytoma,[9] suggesting that changes in PRA and NE contribute to diurnal changes in BP.

Our study subjects had distinct circadian rhythms of NE; NE levels were highest in the early morning and decreased during the day, followed by a more pronounced, sleep-related nocturnal decrease during the initial hours of sleep in both groups. However, both patients with EH and control subjects failed to demonstrate a further reduction during the later hours of sleep. Mean NE levels were high in the EH group throughout the 24-hour study period, and the differences between the EH group and the control group were significant at about 50% of the time points sampled throughout the 24-hour cycle. These observations confirm and add the dimension of time to studies using single time-point sampling that have reported elevated NE in young EH subjects.[1,10] Thus, the multiple sampling techniques may offer a more sensitive index of the relation between sympathetic nervous system activity and control of BP.

In 2 previous reports 24-hour NE levels were assessed in patients with EH. Liebau and Manitius[11] found no difference between EH and control subjects in NE levels in the morning and evening, a period hardly sufficient for representation of the 24-hour activity of the sympathetic nervous system. Zadik et al[12] could not find differences in integrated 24-hour NE levels determined by continuous sampling in ambulant subjects with EH. This study incorporated a higher sodium intake (200 mEq/24 hours), a wider age range of subjects (8.5 to 61 years) and a racial population different from that in our study. The higher 24-hour NE levels in our patients with EH may not be pertinent to the general EH population, but should be viewed as representative of a younger group with perhaps a shorter duration of EH.

The enhanced sympathetic tone in younger patients with EH may be a factor to their higher 24-hour BP values. However, caution must be applied in inferring a cause-effect relation or biologic significance from the study. The differences in NE levels between EH and control subjects may not be of sufficient magnitude to alter BP. Infusion studies of NE in man to create increments in NE in the 30- to 60-pg/ml range have not altered BP.[13] These were short-term studies, however, that may not reflect a longer-term influence of NE on BP regulation. Cardiovascular variables that may reflect increased sympathetic nervous system activity, such as pulse rate, were not monitored at 20-minute intervals in this study. Baseline pulse rate, however, was higher in patients with EH than in control subjects.

A diurnal rhythm of PRA was present in our control subjects, with highest values between 0200 and 0800 hours and lowest values from 1800 hours through the first part of sleep. The circadian rhythm of PRA has control mechanisms of renin release, including sodium-volume homeostasis and BP.[14–16] Circadian periodicity of PRA may best relate to the central nervous system's control of renin release as β-adrenergic blockade abolished the nocturnal increase in PRA.[17] Our patients with EH had a circadian pattern of PRA similar to that of the control subjects, but a much greater variance in PRA values existed between individual time points. EH patients also had higher mean PRA levels compared with control subjects throughout most of the 24-hour period. Two of the 9 patients with EH did, however, have circadian PRA values that were indistinguishable from those of the control subjects, suggesting that with a larger population of persons with EH, distinct subgroups of PRA periodicity may emerge. The enhanced 24-hour sympathetic tone in most of our patients with EH may explain the high PRA levels. The release of renin is influenced by sympathetic outflow[18] and a positive correlation between NE and PRA has been shown in several studies in patients with EH.[19,20] Although PRA did not correlate with NE or mean BP in our patients, a contributory role for the higher PRA levels in modulation of higher vascular tone in those with EH cannot be excluded.

Role of Prostaglandins in the Renal Handling of a Salt Load in Essential Hypertension

BRUNO TRIMARCO, MD, ANTONIO DE SIMONE, MD, ALBERTO CUOCOLO, MD, BRUNO RICCIARDELLI, MD, MASSIMO VOLPE, MD, PAOLA PATRIGNANI, MD, LUIGI SACCÀ, MD and MARIO CONDORELLI, MD

Renal function and systemic hemodynamics were assessed in 10 hypertensive patients and in 10 age-matched normotensive subjects during control conditions (80 mEq of sodium/day) and after a salt load, either alone (480 mEq/day) or combined with indomethacin or sulindac. Indomethacin was used to induce ubiquitous inhibition of prostaglandin synthesis and sulindac to inhibit prostaglandin synthesis in all tissues except the kidney. Under control conditions there was no significant difference between the 2 groups in any measurement except blood pressure and total peripheral resistance. Also, the changes induced by salt load in the 2 groups were comparable. However, after indomethacin administration, only hypertensive patients showed a significant reduction in the 24-hour sodium excretion (from 417 ± 61 to 317 ± 49 mEq, $p < 0.05$), so that the difference between this value and the corresponding value of normotensive subjects (453 ± 79 mEq) became significant ($p < 0.05$). The changes in sodium excretion in hypertensive patients were significantly correlated with the changes in renal plasma flow ($r = 0.803$, $p < 0.01$). However, cardiac output and renal blood flow showed a similar pattern in normal and hypertensive persons. Finally, after the addition of sulindac to salt load, the differences in the 24-hour sodium excretion vanished. These results were also confirmed in an ancillary study performed, using the same protocol, in 10 other hypertensive patients using ibuprofen rather than indomethacin. Our data suggest that renal prostaglandins participate in renal disposal of chronic salt load in hypertensive patients but not in normal persons. (Am J Cardiol 1985; 55:116–121)

Although the natriuretic response to a sodium load in patients with essential hypertension changes throughout life, the variability of this response has not been explained. Prostaglandins are gaining recognition as important modulators of hemodynamic and excretory function in the mammalian kidney.[1–3] Therefore, in the present study we investigated the role of renal and extrarenal prostaglandins in the handling of a sodium load by the kidney in patients with established hypertension. For this purpose, we assessed in normal subjects and in hypertensive patients the effects of indomethacin and sulindac on sodium and potassium excretion, urine output and renal and systemic hemodynamics. Both indomethacin and sulindac are inhibitors of prostaglandin synthesis. However, indomethacin has a diffuse action, whereas sulindac has been reported to possess a sparing effect on prostaglandin synthesis in the kidney,[4,5] probably due to the absence of the active form of the drug in this organ. Because indomethacin induces vasoconstriction independent of its effect on fatty acid cyclooxygenase,[6] we repeated the study in another group of hypertensive patients using ibuprofen in order to clarify whether the results observed with indomethacin were entirely to be ascribed to prostaglandin synthesis inhibition.

Methods

Subjects and procedures: The study was carried out in 20 volunteers (15 men, 5 women). Ten were patients with mild essential hypertension. They were 17 to 56 years old (mean age 32 ± 2). Their mean body weight was 72 ± 3 kg. All had an average supine diastolic blood pressure (BP), measured on 4 occasions at least 1 week apart, of 95 to 110 mm Hg. The other 10 volunteers were normal subjects and constituted the control group. They were 18 to 54 years old (mean age 30 ± 4). Their mean body weight was 72 ± 2 kg. Secondary forms of hyper-

tension were ruled out on the basis of the history, physical examination and routine screening tests. Patients with major diseases other than hypertension were excluded from the study. BP was measured with subjects in the supine position on a comfortable bed and according to the recommendations of the American Heart Association.[7] No patient had been taking any drug for at least 2 weeks before the study was begun. Subjects were asked not to take any other medications during the course of the study and to fast and abstain from fluid for 12 hours before the study. In the week preceding the study as well as throughout the study, each subject was given a diet containing 80 mEq/day of sodium and 70 mEq/day of potassium. Personal food preferences were followed as closely as possible.

The subjects were initially studied under control conditions. On the day before the test, the 24-hour urine samples were collected and 3 blood samples were drawn 12 hours apart in order to measure 24-hour urine output, urinary sodium and potassium excretion and glomerular filtration rate (GFR) as creatinine clearance. On the day of testing procedure, at 9 AM, BP and heart rate were recorded after 15 minutes of recumbency; an M-mode echocardiogram was also performed to estimate cardiac output. Renal plasma flow (RPF) was then determined as p-aminohyppurate clearance as previously described.[8] Furthermore, plasma renin activity and aldosterone concentration were measured in the supine position and after 2 hours in the upright position. Then, the daily diet was supplemented with 4 doses of 100 mmol of cristalline sodium chloride wrapped by wafer to yield a total amount of 480 mEq/day of sodium intake. On the fifth day of high sodium intake, all measurements were repeated. Then, all subjects received either indomethacin or sulindac in a randomized fashion for 3 days (orally administered indomethacin, 50 mg twice on the first day, 50 mg 3 times on the second day and 50 mg 2 hours before starting the procedure on the third day; orally administered sulindac, 200 mg twice on the first day, 200 mg 3 times on the second day and 200 mg 2 hours before starting the testing procedure on the third day). A short treatment period was used because of the possible attenuation of the inhibitory effect on prostaglandin synthesis despite sustained drug administration.[9] After 8 days of high sodium intake, all measurements were repeated. Finally, after a 2-day washout period (ninth and tenth days), the subjects received the other pharmacologic treatment (indomethacin or sulindac; eleventh, twelfth and thirteenth day) and measurements were again repeated on the thirteenth day of high sodium intake. The administered inhibitor was known only to the trial coordinator and measurements were observer-blind. The adequacy of prostaglandin synthesis inhibition induced by the different pharmacologic treatments was assessed through radioimmunoassay of serum thromboxane (Tx) B_2, which reflects thrombin-induced activation of platelet TxA_2 production during whole blood clotting.[10]

Study with ibuprofen: The study was carried out in 10 additional patients (6 men, 4 women) with mild essential hypertension as previously defined. They were 20 to 49 years old (mean 33 ± 2) and had a mean body weight of 74 ± 5 kg. They were asked to follow the same guidelines pertaining to diet, personal habits and drug intake as patients in the other 2 groups. The subjects were initially studied under control conditions. The same procedures were followed as in the previous 2 studies, both on the test days and on the days before testing procedures. Then, the daily diet was supplemented with sodium chloride as already described and each subject was studied again on the fifth day of high sodium intake. Finally, ibuprofen was administered orally for a 3-day period (400 mg twice on the first day, 400 mg 3 times on the second day and 400 mg 2 hours before starting the test procedure on the third day), and all measurements were repeated on the eighth day of high sodium intake.

Analyses: Plasma renin activity was measured according to the method described by Menard and Catt[11] (sensitivity 5 ± 0.4 pg/tube Ang. I, i.e., plasma renin activity 0.06 ng/ml/hour) and plasma aldosterone concentration according to the method described by McKenzie and Clements[12] (sensitivity 6 ± 1 pg/ml). M-mode echocardiography was performed as previously described.[13] The tracings were coded and read by 2 observers in a double-blind fashion.

Either 1-way or 2-way analysis of variance was used as appropriate. Data are expressed as mean ± standard error of the mean.

Results

As expected, during control conditions hypertensive patients showed only BP and total peripheral resistance (TPR) higher than normotensive subjects (Table I, Fig. 1 and 2). In normotensive subjects, high sodium intake induced a significant increase in cardiac output and in RPF (Fig. 1) as well as in the 24-hour urine output and sodium excretion (Fig. 2). BP and heart rate did not change significantly (Table I). Plasma renin activity and aldosterone concentrations, both supine and upright, decreased significantly (Table I), while the changes in

24-hour urinary potassium excretion and GFR were not statistically significant (Fig. 2, Table I). In hypertensive patients, high sodium intake induced changes similar in magnitude to those observed in normal subjects, so that the differences between the 2 groups were the same as those found under control conditions (Table I, Fig. 1). The effects of indomethacin and sulindac on the responses to high sodium intake were not affected by the sequence of drug administration. Therefore, the results obtained when indomethacin was used as the first treatment (eighth day study) were pooled with those obtained when the same drug was used as the second treatment (thirteenth day). Also, the data pertaining to sulindac administration were pooled. Platelet cyclooxygenase activity was inhibited by more than 90% after each of the 2 treatments.

In normal subjects, none of the considered variables changed significantly when indomethacin was added to high sodium intake (Table I, Fig. 1 and 2). However, the significant increase in cardiac output and RPF induced by sodium load alone was lost after indomethacin administration. In hypertensive patients, indomethacin induced a significant increase in BP compared with either of the 2 previous stages of the protocol (Table I). This increase in BP apparently results from a sharp increase in TPR, which became significantly higher than the TPR in the previous stages. Cardiac output significantly decreased from the values found during the high sodium intake alone, and it was no longer different from the control values. Also, RPF decreased in 8 of 10 patients compared with values during high sodium intake alone, although the mean decrease did not reach statistical significance. These hemodynamic changes were accompanied by a significant reduction in the 24-hour urine excretion. In hypertensive patients, but not in normotensive subjects, a significant correlation was found between the changes in RPF and those in sodium excretion induced by indomethacin administration during high sodium intake ($r = 0.803$, $p < 0.01$). Finally, in normal subjects the addition of sulindac to high-sodium diet induced changes similar to those observed with indomethacin (Fig. 1).

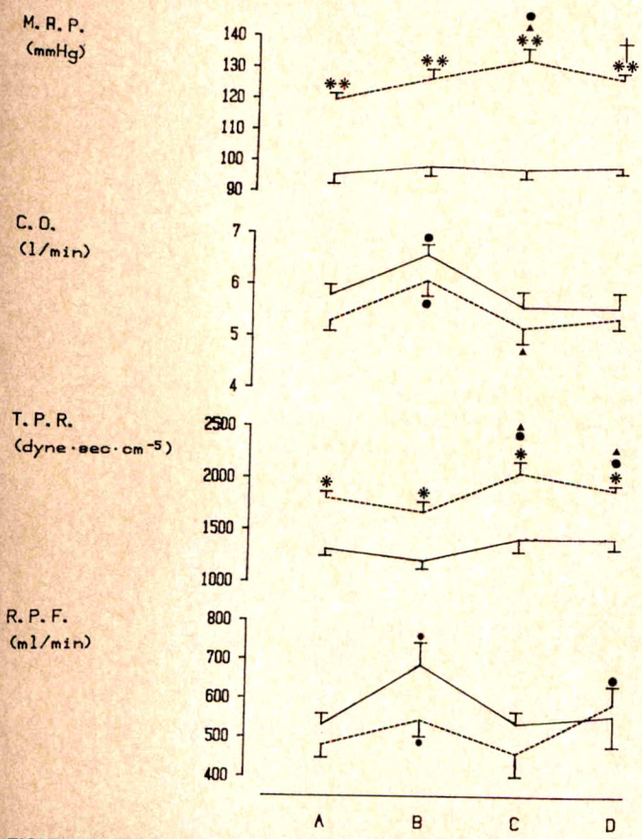

FIGURE 1. Mean arterial pressure (M.A.P.), cardiac output (C.O.), total peripheral resistance (T.P.R.) and renal plasma flow (R.P.F.) under control conditions (**A**) and during salt load, alone (**B**) or associated with indomethacin (**C**) or sulindac (**D**) in normal subjects (**continuous line**) and in hypertensive patients (**dotted line**). Each **point** represents the mean ± standard error of the mean; n = 10. Different from the corresponding value obtained in normal subjects: * $p < 0.05$ and ** $p < 0.01$; ● different from the corresponding value in the same group in control conditions (80-mEq/day sodium diet) ($p < 0.05$); ▲ different from the corresponding value in the same group with 480-mEq/day sodium diet: $p < 0.05$; † different from the corresponding value in the same group with 480-mEq/day sodium diet plus indomethacin: $p < 0.05$.

In contrast, in hypertensive patients the administration of sulindac during the high-sodium diet induced changes different from those observed with indomethacin. In particular, we did not observe the significant increase in BP found during indomethacin treatment. Furthermore, the increase in TPR and the decrease in cardiac output were less marked. During sulindac treatment, hypertensive patients, as a group, showed higher RPFs than in previous stages of our protocol. The mean RPF in hypertensive patients during high sodium intake was similar to that found when sulindac was added. In both stages, RPF was higher than the mean value found during low sodium intake as well as during indomethacin administration. However, probably because of the heterogeneous response of the individual patients, no significant difference was reached when indomethacin was compared with sulindac. On the other hand, statistical significance was reached when comparing the percentage of cardiac output delivered to the kidney in these 2 stages of our study (15 ± 4% vs 25 ± 2%, $p < 0.05$). Furthermore, the ratio of RPF to cardiac output became significantly higher when sulindac was added to the high sodium intake also as compared with the high sodium intake alone (25 ± 2% vs 20 ± 2%, $p < 0.05$). In addition, the reduction in the 24-hour urinary sodium excretion observed after sulindac treatment was less marked than that found after indomethacin. Therefore, this response can not be differentiated either from that observed in the same group of patients during high sodium intake alone or from that observed in normal subjects during sulindac administration (Fig. 2).

Study with ibuprofen: Under control conditions, no significant difference was detectable in all the considered parameters between the hypertensive patients enrolled in this study (Table II, Fig. 3) and those participating in the study previously described. In the ibuprofen study, the high sodium intake alone elicited changes in the measurements similar to those observed both in normotensive and in hypertensive subjects in the previous study (Table II, Fig. 3). Furthermore, addition of ibuprofen to the sodium load induced changes

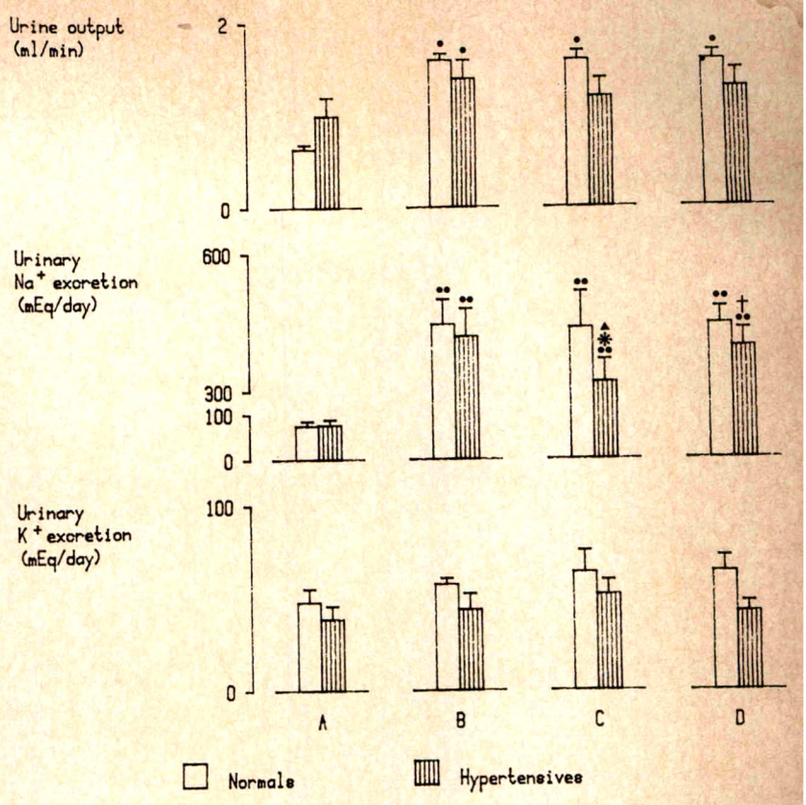

FIGURE 2. Twenty-four-hour urine output and urinary sodium and potassium excretion in control conditions (**A**) and during salt load, alone (**B**) or associated with indomethacin (**C**) or sulindac (**D**) in normotensive subjects and in hypertensive patients. Each **bar** represents mean ± standard error of the mean, n = 10. Statistical analysis as in Figure 1. in hemodynamics similar to those previously observed in hypertensive patients treated with indomethacin (Table II) and a significant reduction in the 24-hour urine output and urinary sodium excretion (Fig. 3).

Discussion

Two experimental approaches are available in order to investigate the possibility that endogenous prostaglandins participate in pathophysiological phenomena: prostaglandin assay in blood, urine or tissue specimens, and administration of drugs that inhibit prostaglandin synthesis. Measurement of prostaglandin concentration may provide more complete information about the role of these substances, because it indicates both the specific prostaglandin involved and the degree of the evoked change in their concentration. However, the reproducibility and the sensitivity of prostaglandin assay are limited by several factors.[3,14] Furthermore, it remains uncertain whether an observed change in prostaglandin levels represents a cause or merely a consequence of a given phenomenon. Given the above limitations of prostaglandin assay, in this study we chose the use of prostaglandin synthesis inhibitors to test the hypothesis that prostaglandins play a role in renal sodium handling in essential hypertension. In particular, we used indomethacin and sulindac in an attempt to investigate the relative roles of renal and extrarenal prostaglandins in the renal handling of a salt load. Because we could duplicate the results obtained using indomethacin with ibuprofen, it appears reasonable to ascribe the changes observed in our patients with

the above drugs to concurrent changes in prostaglandin synthesis rather than to nonspecific pharmacologic properties of these drugs independent of prostaglandin synthesis. Finally, the possibility of incomplete prostaglandin synthesis inhibition is unlikely because our data from TxB_2 assay show that a sufficient inhibition of cyclooxygenase activity was achieved in our patients.

In our study, an increased sodium intake elicited similar changes in hemodynamics and renal function both in normal and hypertensive subjects. In particular, in agreement with a previous study,[15] the response of cardiac output and urinary sodium excretion was comparable in the 2 groups. In contrast, when prostaglandin synthesis inhibitors were added to the high sodium diet, hypertensive patients responded differently from normotensive subjects. After indomethacin or ibuprofen treatment, the 24-hour renal sodium excretion sharply decreased and BP increased in hypertensive but not in normotensive subjects. In contrast, after addition of sulindac to the sodium load, we observed in hypertensive patients a 24-hour sodium excretion level comparable to that of normal subjects. These observations indicate that the prostaglandin system plays a role in favoring the renal disposal of a chronic sodium load in hypertensive patients but not in normotensive subjects, and suggest that renal prostaglandins are mainly responsible for this phenomenon. Furthermore, the lack of significant changes in BP in hypertensive patients during sulindac administration suggests that the increase in BP observed during indomethacin administration is due to the reduced sodium excretion rather than to the direct effect of indomethacin or ibuprofen on prostaglandin control of vascular tone, as described by previous investigators.[16] Finally, our data do not reveal the mechanism underlying the impairment of the renal handling of a salt load during indomethacin administration. Our study shows that both indomethacin and ibuprofen normalized the increased RPF induced by the high sodium intake, in both normotensive and in hypertensive subjects, although only hypertensive patients showed a concurrent reduction in sodium excretion. Thus, in normal subjects the kidney maintains a normal rate of sodium excretion even in the face of a reduced RPF after inhibition of prostaglandin synthesis. This indicates that the increase of the RPF after a sodium load is not a prerequisite for the enhanced renal excretion of sodium to occur. In hypertensive patients, on the other hand, the simultaneous reduction of both RPF and sodium excretion makes it impossible to ascertain whether the 2 phenomena are independent or linked by a cause-effect relation. The existence of a significant direct correlation between sodium excretion and RPF after indomethacin in hypertensive patients indirectly supports the latter interpretation. However, renal vasodilatation is only 1 mechanism of prostaglandin-mediated natriuresis. It has been reported that prostaglandin E_2 augments natriuresis in the canine kidney, that is maximally vasodilatated with acetylcholine.[17] Furthermore, in vitro studies have shown that prostaglandins can influence

transepithelial transport of ions both in the thick ascending limb of Henle's loop and in the collecting tube.[18–20] Finally, the observation that during both indomethacin and ibuprofen treatments, but not during sulindac administration, there was a reduction in GFR indicates that also a reduction in the filtered load of sodium may represent an alternative mechanism for the reduced natriuresis after inhibition of renal cyclooxygenase.

The possibility that prostaglandins improve renal function also by mechanisms not involving changes in RPF may offer some advantages in a tentative explanation of the data observed in established hypertensives. Bianchi et al[21] found in normotensive subjects who were first-degree relatives of essential hypertensive persons an RPF higher than that in age-matched normal subjects, and hypothesized that this may represent a compensatory mechanism for a primary, still unidentified, kidney defect in such subjects who are at an increased risk of essential hypertension. In similar subjects, Grim et al[22] demonstrated a blunted natriuretic response to salt load. Therefore, it appears unlikely that an increased RPF, which fails to normalize the natriuretic response in the young subjects, could succeed in older patients with probable vascular changes secondary to long-lasting hypertension. Whatever the case, the observation that the inhibition of renal prostaglandin synthesis impairs sodium excretion in hypertensive patients suggests that prostaglandins exert a pivotal role in renal sodium handling in these patients also in physiologic conditions, i.e., during salt load in which their inhibition has no effect on sodium excretion in normal subjects.

Immediate Converting-Enzyme Inhibition with Intravenous Enalapril in Chronic Congestive Heart Failure

SPENCER H. KUBO, MD, ROBERT J. CODY, MD, JOHN H. LARAGH, MD, XAVIER E. PRIDA, MD, STEVEN A. ATLAS, MD, ZHUNG YUAN, MD, and JEAN E. SEALEY, DSc

To test the hypothesis that intravenous enalapril is a useful pharmacologic probe of the renin angiotensin system, intravenous enalapril was administered to 9 patients with severe congestive heart failure (CHF). This produced abrupt and complete blockade of converting enzyme, with peak effect occurring at 30 minutes, as reflected by increases of plasma renin activity (from 16.8 ± 6 to 86.6 ± 23 ng/ml/hour) and decreases of plasma aldosterone levels (from 46 ± 14 to 25 ± 6 ng%) (both $p < 0.05$). With reduction of angiotensin II–mediated vasoconstriction, systemic vascular resistance decreased markedly (from 1,974 ± 233 to 1,400 ± 136 dyne s cm^{-5}) and cardiac index was improved (from 1.88 ± 0.9 to 2.20 ± 0.21 liters/min/m^2) (both $p < 0.05$). The time course of angiotensin II levels suggested that the lack of a cumulative effect from additive doses of intravenous enalapril was a reflection of complete inhibition of converting enzyme. One patient did not respond to enalapril; despite comparable hemodynamic severity of CHF, the renin-angiotensin system was not activated in this patient. Thus, intravenous enalapril is capable of rapid and complete inhibition of converting enzyme for the accurate assessment of angiotensin II–mediated vasoconstriction in patients with severe CHF.

(Am J Cardiol 1985;55:122–126)

Despite the large number of drugs that induce vasodilatation in congestive heart failure (CHF), those that act by more readily defined mechanisms may also clarify pathophysiology and ultimately lead to more specific therapy.[1,2] One important vasoconstrictor mechanism in severe CHF is activation of the renin-angiotensin system,[3–5] mediated by the potent vasoconstriction of angiotensin II and the sodium and water retention of aldosterone. However, angiotensin and aldosterone are not uniformly stimulated in all patients with CHF.[4] The converting-enzyme inhibitor captopril has been a useful pharmacologic probe to determine the extent of this activity.[6,7] However, the peak effect and completeness of converting-enzyme inhibition are difficult to assess accurately with an orally administered agent. A second-generation converting enzyme inhibitor, enalapril (MK-421), may be another useful probe; however, enalapril is a pro-drug that must be de-esterified with a delayed peak effect of 6 to 8 hours.[8,9] These limitations may be avoided with the intravenous administration of an active drug. In the present study, we characterize the hemodynamic and neurohormonal responses to intravenous enalapril (MK-422) in patients with severe CHF, to assess the usefulness of intravenous enalapril as a pharmacologic probe of the renin-angiotensin system and to determine the degree to which the renin-angiotensin system can be abruptly and completely suppressed.

Methods

The study consisted of 9 patients (7 men, 2 women, aged 38 to 73 years, mean 58) with severe, chronic CHF (New York Heart Association class III or IV) refractory to digitalis and diuretic drugs. Four patients had coronary heart disease (ischemic cardiomyopathy) and 5 had idiopathic cardiomyopathy. No patient had systemic hypertension or recent myocardial infarction and all were clinically stable at the time of the study. The patients were admitted to the Clinical Research Center and placed on a 100-mEq sodium diet. All previous vasodilator therapy was discontinued for at least 4

days. Because of the severity of CHF, digoxin and diuretic drugs were continued at constant doses, although neither was administered on the day of the invasive hemodynamic study.

Hemodynamic study: After an overnight fast, a triple-lumen thermodilution catheter was placed under fluoroscopic guidance. Right atrial and pulmonary capillary wedge pressures were recorded continuously. Thermodilution cardiac output was determined in triplicate and expressed as cardiac index, corrected for body surface area. Arterial blood pressure was continuously recorded after a cannula was placed in a radial artery. Heart rate was monitored from a precordial electrocardiographic lead. Systemic vascular resistance and stroke volume index were calculated from standard formulas.[10]

Patients were allowed to rest for 45 minutes between catheter insertion and baseline hemodynamic determinations and blood sampling to measure plasma renin activity, aldosterone, norepinephrine and angiotensin II levels. A second control measurement was obtained after 30 minutes to ensure stable baseline values.

Patients were given 2 doses of intravenous enalapril to assess its cumulative effect. Based on preliminary data, we administered 1.25 mg as the first dose, followed by 2.5 mg. Because of marked hypotension in the first patient given this regimen, the dosing schedule was changed to 0.625 mg and 1.25 mg for all subsequent patients. After the first dose, hemodynamic values and blood samples to measure plasma renin activity, aldosterone, norepinephrine and angiotensin II levels were taken every 15 minutes for 60 minutes, and then at 90 minutes. Measurements were taken every 30 minutes for 90 minutes after the second dose. Eight patients showed a greater than 15% decrease of systemic vascular resistance, and these patients were analyzed together; the data of the only nonresponder is presented separately.

Hormonal assay: Plasma renin activity, plasma aldosterone, norepinephrine and angiotensin II levels were determined by radioimmunoassay.[11–13] Plasma renin activity was estimated by the generation of angiotensin I in vitro. Angiotensin II was separated from angiotensin I by high-pressure liquid chromatography and measured by radioimmunoassay. Norepinephrine levels were determined by radioenzymatic assay.

Statistical analysis: Values for the group are represented as mean ± standard error of the mean. Statistical determinations were by analysis of variance, with peak response compared to baseline values. Changes were considered to be statistically significant at the $p < 0.05$ level.

Results

The neurohormonal and hemodynamic effects of intravenous enalapril are shown in Figure 1. The baseline renin-angiotensin system activity was increased, with a mean plasma renin activity of 16.8 ± 6 ng/ml/hour, plasma aldosterone of 46 ± 14 ng% and angiotensin II of 68 ± 12 pg/ml. After the first bolus injection, there was an immediate and marked increase in plasma renin activity, with a more than 300% increase as early as 15 minutes. Peak response occurred at 30 minutes, increasing from a baseline value of 16.8 ± 6 ng/ml/hour to 86.6 ± 23 ng/ml/hour ($p < 0.05$). This effect was maintained with minor attenuation so that plasma renin activity was 72.4 ± 16 ng/ml/hour at the end of the 90-minute observation period. There was a progressive, time-delayed decrease in circulating plasma aldosterone levels, from a baseline of 46 ± 14 ng% to a nadir of 25 ± 6 ng% at 90 minutes after the first dose ($p < 0.05$). Norepinephrine levels were increased at baseline (561 ± 95 pg/ml), consistent with severe CHF, and did not show any significant change despite abrupt converting-enzyme inhibition.

The hemodynamic changes after intravenous enalapril therapy were also abrupt and peak changes occurred

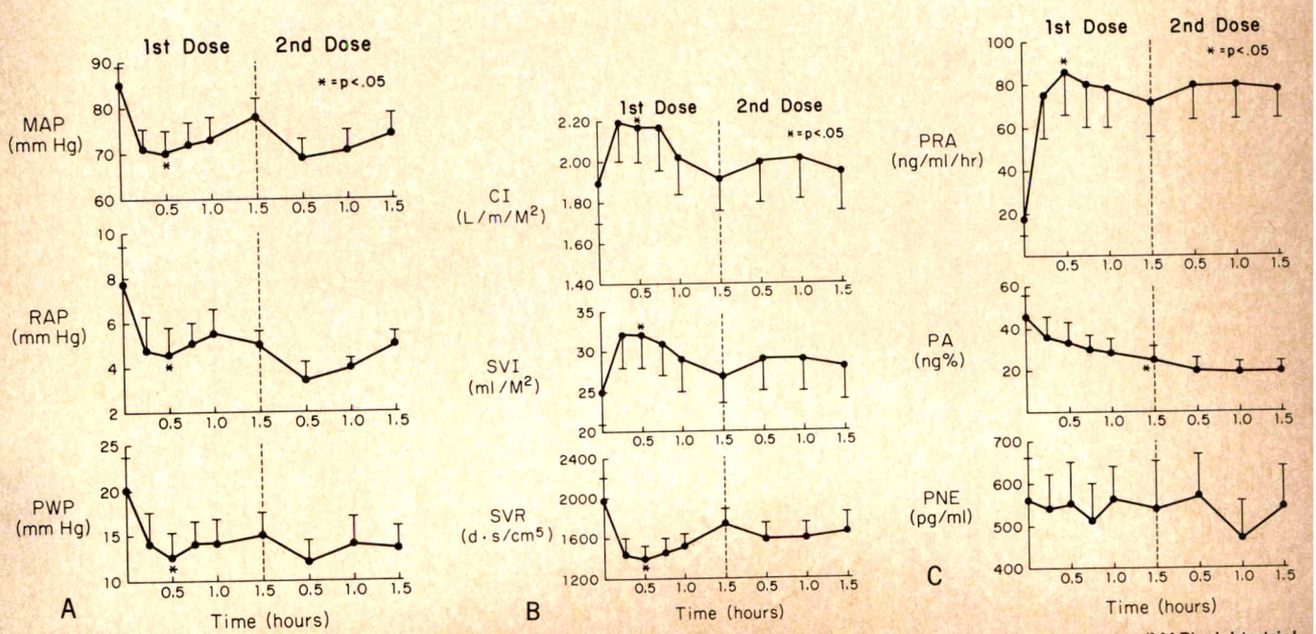

FIGURE 1. Hemodynamic and neurohormonal responses to bolus injections of intravenous enalapril. **A,** mean arterial pressure (MAP), right atrial pressure (RAP) and pulmonary capillary wedge pressure (PWP). **B,** cardiac index (CI), stroke volume index (SVI) and systemic vascular resistance (SVR). **C,** plasma renin activity (PRA), plasma aldosterone (PA) and plasma norepinephrine (PNE). Values are mean ± standard error of the mean.

TABLE I Hemodynamic and Neurohormonal Response to Intravenous Enalapril in a Nonresponder

	Baseline	15 min	30 min	60 min	90 min
MAP (mm Hg)	88	89	87	82	78
PWP (mm Hg)	25	21	18	19	24
CI (liters/m/m^2)	1.49	1.49	1.60	1.56	1.51
SVR (dynes s cm^{-5})	2,304	2,397	2,289	2,141	2,039
PRA (ng/ml/hour)	1.1	1.1	1.1	1.1	1.3
PA (ng%)	19	12	10	8.7	11
AII (pg/ml)	14.9	14.4	14.4	10.9	31.8
PNE (pg/ml)	842	753	654	807	932

AII = angiotensin II; other abbreviations as in Figure 1.

at 30 minutes. There was a prompt and marked reduction of systemic vascular resistance, from 1,974 ± 223 to 1,400 ± 136 dynes s cm^{-5}, and mean arterial pressure, from 85 ± 4 to 70 ± 5 mm Hg, at peak response ($p < 0.05$). Likewise, the decrease of right atrial pressure from 8 ± 2 to 5 ± 1 mm Hg and pulmonary wedge pressure from 21 ± 4 to 13 ± 3 mm Hg were both significant at peak response at 30 minutes ($p < 0.05$). Vasodilatation induced by abrupt converting-enzyme inhibition resulted in improved forward flow: Cardiac index increased from 1.88 ± 0.19 to 2.20 ± 0.21 liters/m/m^2 and stroke volume index from 25 ± 4 to 32 ± 4 ml/m^2 at peak response ($p < 0.05$). At the end of the 90-minute observation period, these hemodynamic changes were attenuated.

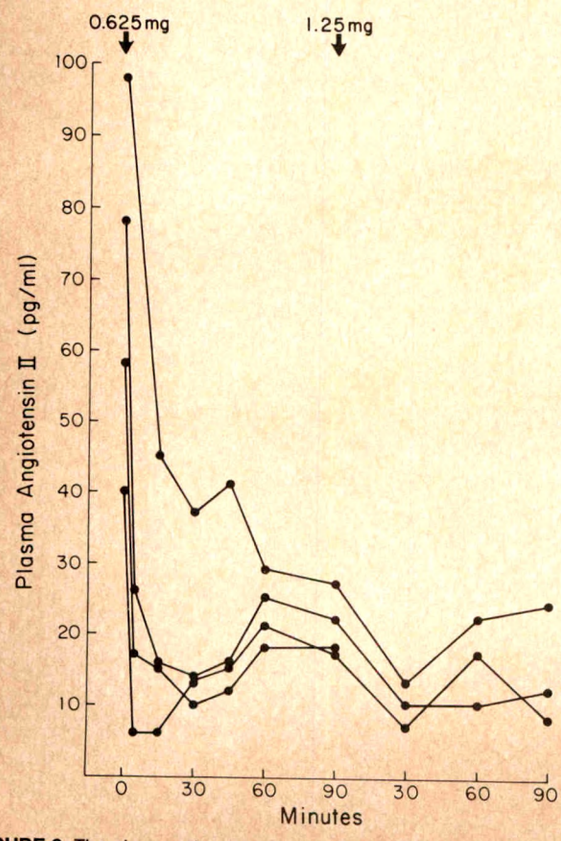

FIGURE 2. The changes in plasma angiotensin II levels after bolus injections of intravenous enalapril in 4 patients.

A second intravenous bolus of enalapril was then given to determine whether a cumulative response would occur and also to document complete converting-enzyme inhibition. After the second dose, the additional changes of plasma renin activity and plasma aldosterone levels were insignificant. All hemodynamic indexes show a trend of response similar to the first dose response, but there were no significant cumulative effects.

The lack of a cumulative response to the second dose of enalapril could represent either acute tachyphylaxis or maximal converting-enzyme inhibition maintained from the first dose. To clarify this issue, we examined the response of angiotensin II levels in 4 patients. Despite a wide range of baseline angiotensin II levels (40 to 98 pg/ml, mean 68 ± 12), angiotensin II decreased to 19 ± 6 pg/ml at 30 minutes. This effect was maintained over 90 minutes with minimal attenuation; after the second dose of enalapril, angiotensin II remained at comparable low levels.

The hemodynamic and neurohormonal changes of the only patient who did not respond to enalapril are listed in Table I. In this patient, the renin-angiotensin system was not activated, as manifest by baseline values for plasma renin activity of 1.1 ng/ml/hour, plasma aldosterone of 19 ng% and angiotensin II of 14.9 pg/ml, all of which are low relative to the other patients and essentially normal. Despite the differences in these baseline neurohormonal measurements, baseline hemodynamic indexes are similar to those of the other patients, suggesting the predominance of an alternate vasoconstrictor mechanism. Administration of intravenous enalapril had virtually no effect, confirming the minor contribution of angiotensin II–mediated vasoconstriction in this patient.

Discussion

The results of the present study demonstrate that the renin-angiotensin system can be abruptly and completely blocked by intravenous bolus injections of an active converting-enzyme inhibitor, enalapril (MK-422). The neurohormonal effects of converting-enzyme inhibition are manifest as early as 15 minutes, with peak effect at 30 minutes. This consists of an abrupt reduction in levels of circulating angiotensin II and an increase in plasma renin activity as a result of the reduction in angiotensin II negative feedback inhibition on renin secretion. In contrast to these abrupt changes,

there was a progressive, time-delayed decrease in the aldosterone level; this has been seen after oral administration of captopril and is related to the longer half-life of circulating aldosterone.[6]

Peak hemodynamic effect also occurred at 30 minutes. The reductions of systemic vascular resistance and mean arterial pressure were generally well tolerated and demonstrated some attenuation by 90 minutes. The magnitude of increases of cardiac index and stroke volume index at peak effect were significant, but were less than those seen with direct vasodilators, such as nitroprusside and the newer inotropic agents.[14] The improvements in forward flow seen with balanced vasodilators represent the net effect of reductions of afterload and reductions of preload. The specific influence of preload reduction with converting-enzyme inhibitors on the subsequent improvement in forward flow, however, has not been clarified.

Despite the rapid vasodilatation and decreases in mean arterial pressure, there was no reflex increase in heart rate. The lack of reflex sympathetic stimulation is confirmed by the lack of significant changes in plasma norepinephrine levels. Several investigators have described profound bradycardia after administration of captopril to some patients with CHF.[15] In the present study, no patient had bradycardia; although the study population was small, this finding suggests that bradycardia will not be a significant problem accompanying angiotensin II withdrawal with intravenous enalapril.

An inverse correlation between serum sodium concentration and plasma renin activity has been reported.[16,17] Our experience with a larger group of 108 patients with CHF confirms this relation.[18] However, this correlation is complex, as many patients with normal sodium levels have high renin levels, and is strongly influenced by diuretic therapy.[17] In the present small study, there was no correlation between sodium concentration and plasma renin activity.

The response of norepinephrine to vasodilator therapy is complex. Although a reduction in norepinephrine levels with long-term captopril therapy have been shown,[19] the response with long-term enalapril therapy has been inconsistent.[9,20] In the present study with intravenous enalapril, norepinephrine levels did not change acutely.

The insignificant hemodynamic and neurohormonal changes after the second bolus injection suggest that there are no cumulative effects of intravenous enalapril. A dose-response relation may be produced if even smaller doses of intravenous enalapril are used. However, the doses used in the present study (0.625 and 1.25 mg) are already low and smaller than the doses (5 to 10 mg) reported to be necessary in patients with hypertension.[21] At these larger doses, it is possible that an alternate mechanism, such as inhibition of bradykinin degradation, is activated. Our data suggest that such large doses may be excessive for patients with CHF and may be associated with adverse side effects.

The reduction in angiotensin II levels after intravenous enalapril treatment directly quantitate the inhibition of converting enzyme. The fact that they remain suppressed for 90 minutes after the first dose and do not show any appreciable change after the second dose strongly suggests complete inhibition of converting enzyme rather than acute tachyphylaxis. This is also helpful in explaining the lack of cumulative hemodynamic and neurohormonal effects from the additive doses. Unlike nonspecific vasodilators such as hydralazine, with which successive doses produce incremental responses, the effectiveness of converting-enzyme inhibitors is based on specific enzymatic inhibition, where dose responsiveness is unlikely.

Although only 1 patient in this small study did not respond to enalapril, this finding emphasizes 3 important features of the renin-angiotensin system and vasoconstrictor mechanisms in chronic CHF: (1) Baseline levels of plasma renin activity, plasma aldosterone and angiotensin II were low, emphasizing that the activation of the renin-angiotensin system in CHF varies from patient to patient.[4] (2) Despite the absence of renin-angiotensin system activation in this patient, hemodynamic severity of CHF and vasoconstriction were similar to those of the other patients in this study, thus supporting the concept of alternate vasoconstrictor mechanisms in CHF.[1] (3) Intravenous enalapril produced no significant hemodynamic or neurohormonal changes, confirming the minor contributions of angiotensin II–mediated vasoconstriction for this patient.

The use of pharmacologic probes, such as rapidly acting converting-enzyme inhibitors, may more accurately profile pathophysiologic mechanisms of vasoconstriction in CHF, so that vasodilator therapy can be specific and directed. As in earlier studies with converting-enzyme inhibitors in patients with CHF,[15] some patients will have marked reductions in blood pressure, so that careful monitoring of the acute hemodynamic effects is important. The present study has shown that intravenous enalapril is a useful pharmacologic probe of the renin-angiotensin system in chronic CHF. With abrupt and complete inhibition of converting enzyme, the contribution of angiotensin II–mediated vasoconstriction to the abnormal hemodynamic state can be assessed accurately.

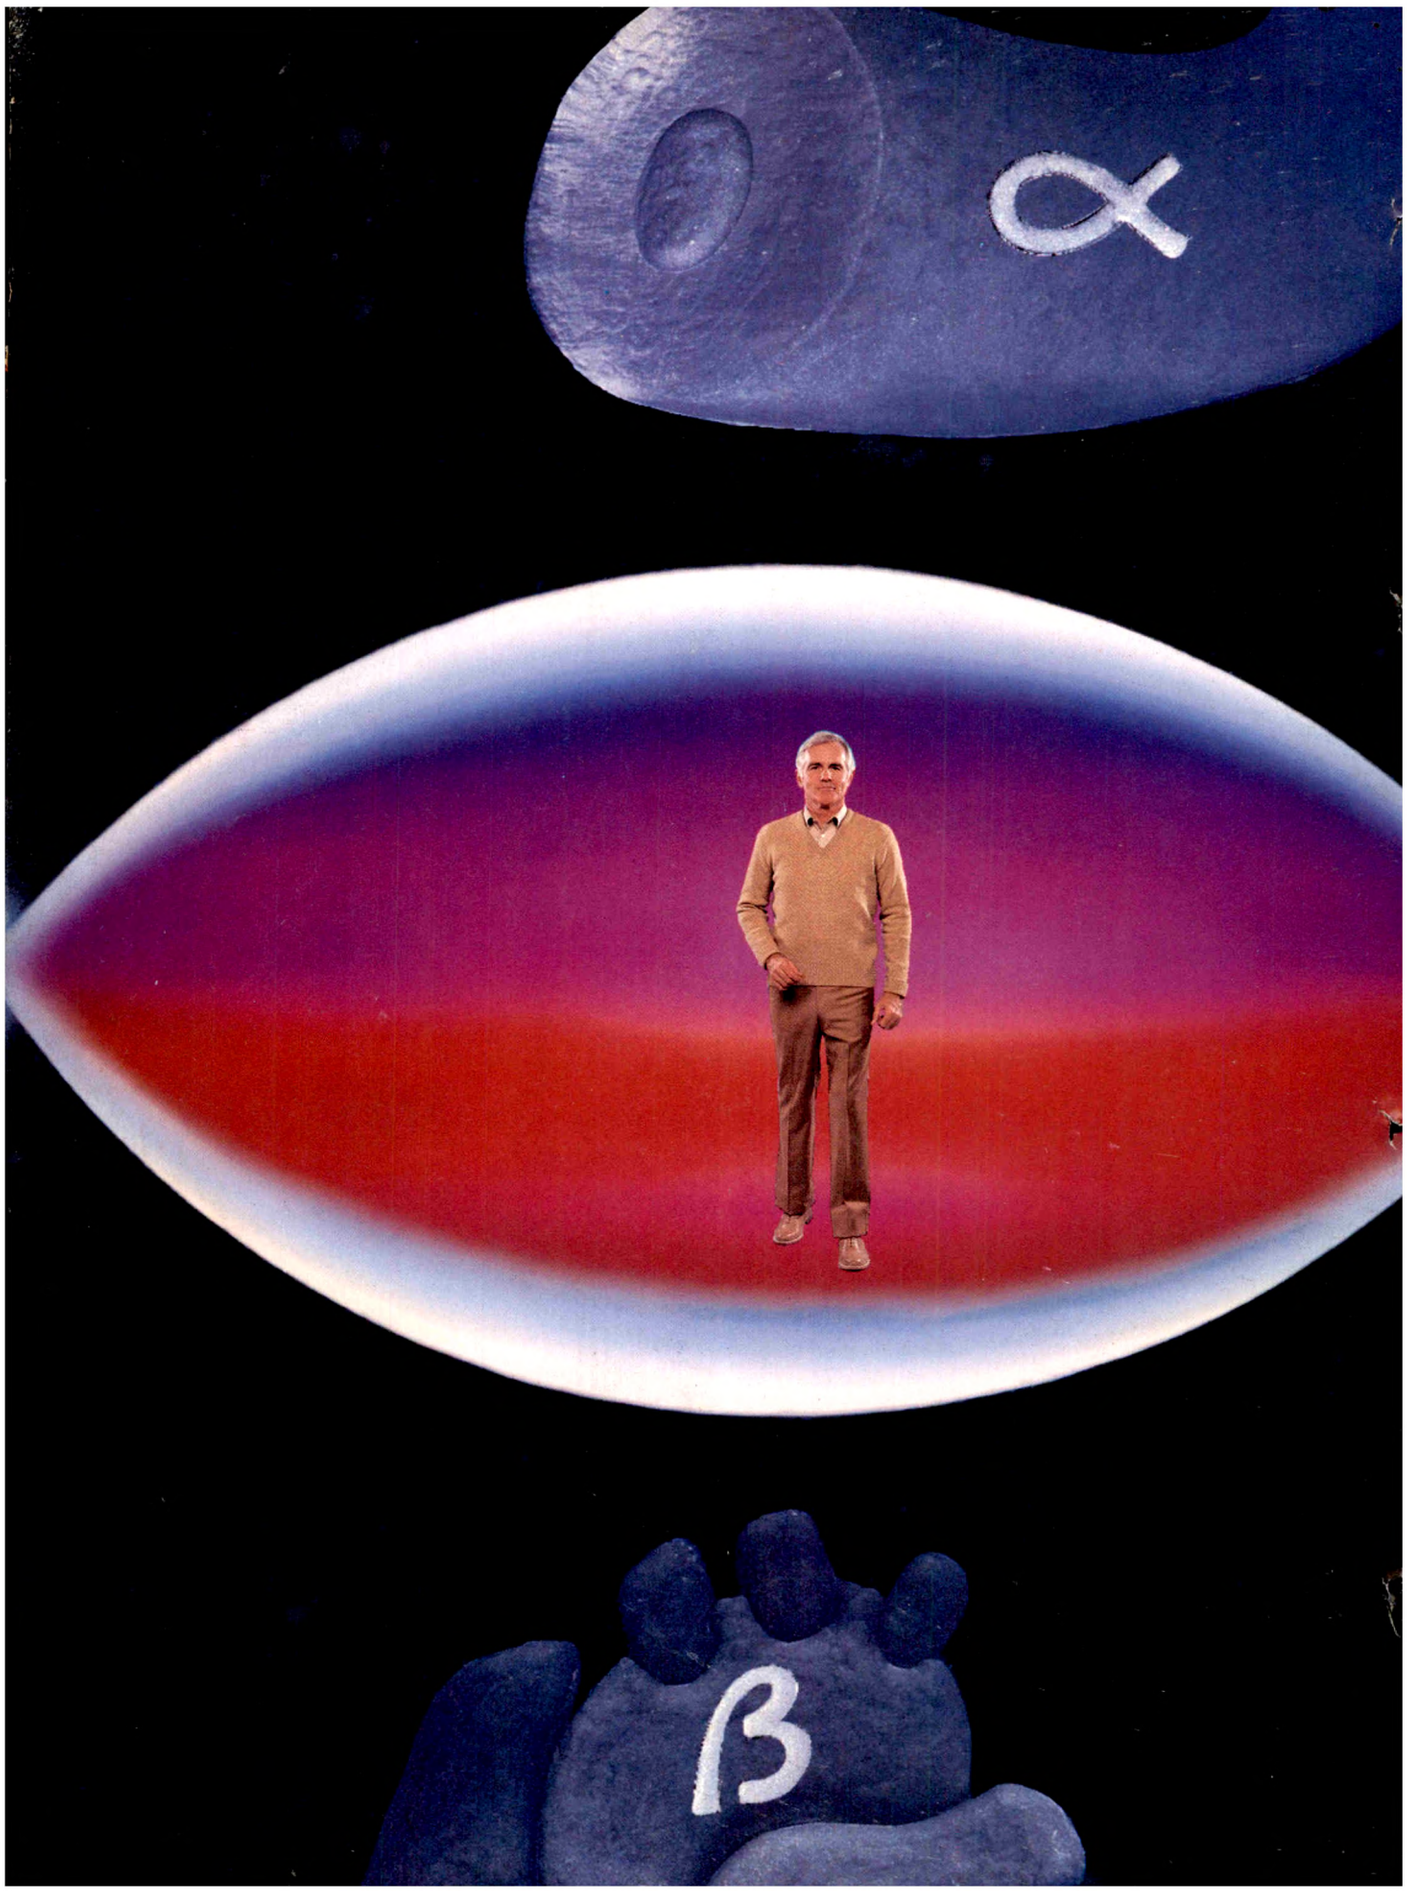
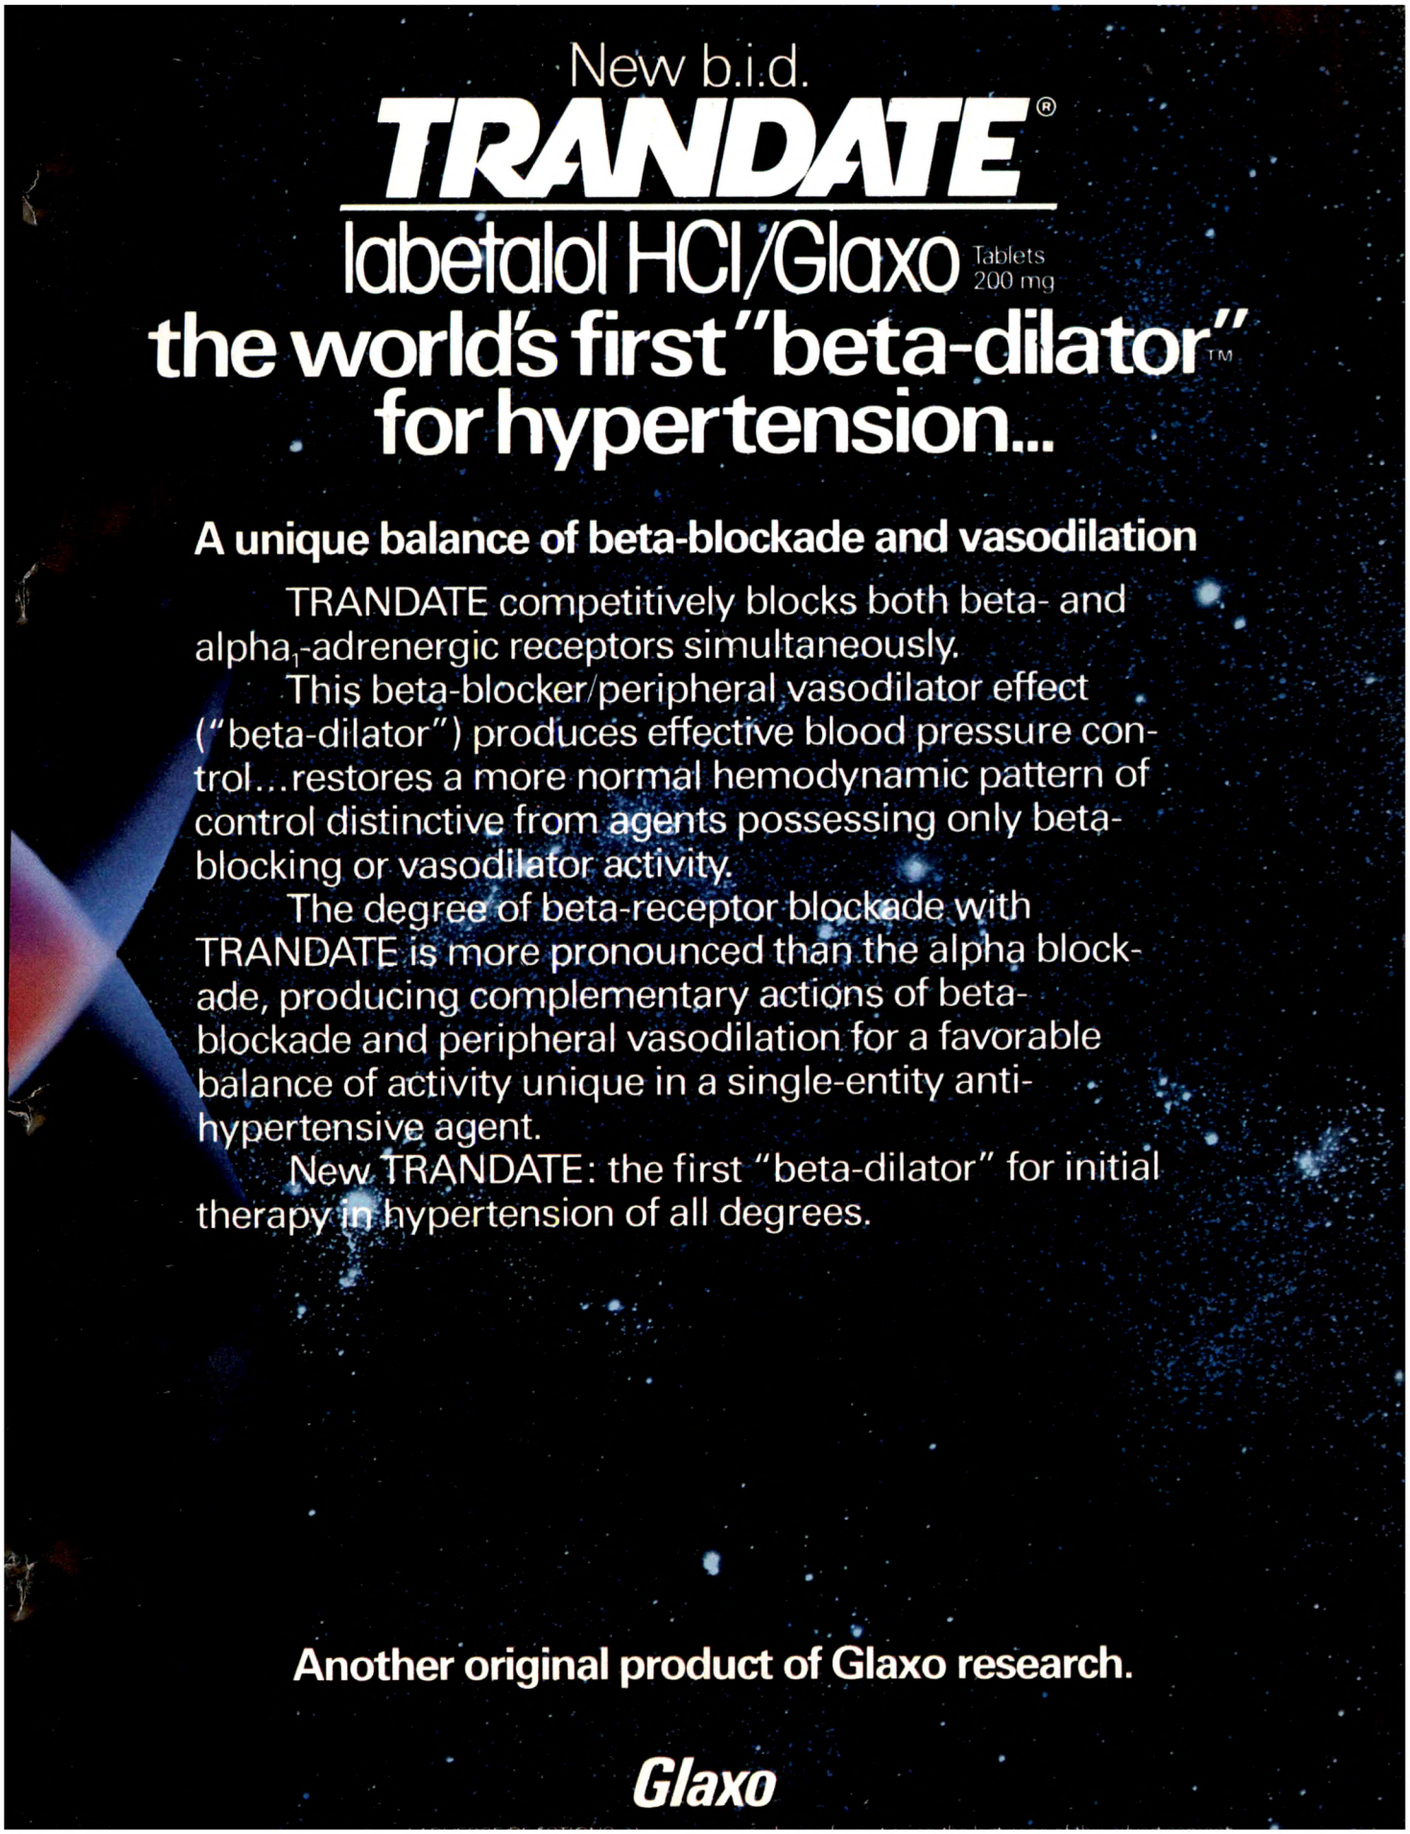
Now, from original Glaxo research:
a new drug, a new class,
a singular new molecule for control of hypertension...



α
β



New b.i.d.
TRANDATE®
labetalol HCl/Glaxo Tablets 200 mg
the world's first "beta-dilator"™ for hypertension...
A unique balance of beta-blockade and vasodilation
TRANDATE competitively blocks both beta- and alpha$_1$-adrenergic receptors simultaneously.
This beta-blocker/peripheral vasodilator effect ("beta-dilator") produces effective blood pressure control...restores a more normal hemodynamic pattern of control distinctive from agents possessing only beta-blocking or vasodilator activity.
The degree of beta-receptor blockade with TRANDATE is more pronounced than the alpha blockade, producing complementary actions of beta-blockade and peripheral vasodilation for a favorable balance of activity unique in a single-entity antihypertensive agent.
New TRANDATE: the first "beta-dilator" for initial therapy in hypertension of all degrees.
Another original product of Glaxo research.

New b.i.d.

TRANDATE®

labetalol HCl/Glaxo Tablets, 200 mg

the world's first "beta-dila for hypertension...

Controls blood pressure without affecting cardiac output

Unlike beta-blockers, TRANDATE treats the basic hem namic defect in hypertension...promptly reduces blood pres by lowering peripheral resistance, while maintaining cardiac put. Significant reductions in both supine and standing BP c on the first day of treatment...without development of tolera

Reduces risk of bradycardia and reflex tachycard

Vasodilator-induced reflex tachycardia has not been re with TRANDATE therapy, nor has significant reduction in h rate. And beta-blocker-induced vasoconstriction does not o with TRANDATE, offering protection against cold extremities

No adverse effect on renal function

TRANDATE produces no substantial alterations in re plasma flow or glomerular filtration rate.

No significant effect on myocardial function

TRANDATE does not depress ventricular function...ca output and stroke volume are maintained.

No significant effect on lipids

Unlike beta-blockers, TRANDATE does not have an ad effect on cholesterol or triglyceride levels.*

*Lipid regulation is not an indication for TRANDATE.

New b.i.d.

TRANDATE®

labetalol HCl/Glaxo Tablets 200 mg

the world's first "beta-dilator"™ for hypertension...

An effective antihypertensive for the elderly

The unique hemodynamic pattern of blood pressure control produced by TRANDATE may be important in treating elderly hypertensives who may already have reduced cardiac and renal function. TRANDATE reduces blood pressure without decreasing cardiac output—or renal blood flow. TRANDATE maintains organ perfusion—avoids the problem of cold extremities.

A proven antihypertensive for black hypertensives

An antihypertensive for young, active patients

TRANDATE allows normal hemodynamic responses to exercise, and is associated with a low incidence of patient fatigue. Impotence is extremely rare with TRANDATE therapy, and the mental confusion associated with central alpha agonists has not been reported.

Simple b.i.d. dosage, dose-related response

Initiation of therapy with TRANDATE is simple. Low doses are used; initiate therapy with 100 mg (1/2 tab) b.i.d. and titrate upward as needed.

Most adverse effects are mild, occur early in treatment, and disappear during the first two weeks*

The most frequently reported reactions to TRANDATE in clinical trials were dizziness (11%) and nausea (6%); less frequent reactions (5% or less): fatigue, dyspepsia, nasal stuffiness, headache, edema, dyspnea, vertigo, rash, and postural hypotension.*

·TRANDATE® Tablets
(labetalol hydrochloride)
BRIEF SUMMARY OF PRESCRIBING INFORMATION

INDICATIONS AND USAGE: TRANDATE® (labetalol hydrochloride) Tablets are indicated in the management of hypertension. TRANDATE Tablets may be used alone or in combination with other antihypertensive agents, especially thiazide and loop diuretics.

CONTRAINDICATIONS: TRANDATE® Tablets are contraindicated in bronchial asthma, overt cardiac failure, greater than first degree heart block, cardiogenic shock, and severe bradycardia (see WARNINGS).

WARNINGS: Cardiac Failure: Sympathetic stimulation is a vital component supporting circulatory function in congestive heart failure. Beta blockade carries a potential hazard of further depressing myocardial contractility and precipitating more severe failure. Although beta-blockers should be avoided in overt congestive heart failure, if necessary, labetalol HCl can be used with caution in patients with a history of heart failure who are well-compensated. Congestive heart failure has been observed in patients receiving labetalol HCl. Labetalol HCl does not abolish the inotropic action of digitalis on heart muscle.

In Patients Without a History of Cardiac Failure: In patients with latent cardiac insufficiency, continued depression of the myocardium with beta-blocking agents over a period of time can in some cases lead to cardiac failure. At the first sign or symptom of impending cardiac failure, patients should be fully digitalized and/or be given a diuretic, and the response observed closely. If cardiac failure continues, despite adequate digitalization and diuretic, TRANDATE® therapy should be withdrawn (gradually, if possible).

Exacerbation of Ischemic Heart Disease Following Abrupt Withdrawal: Angina pectoris has not been reported upon labetalol HCl discontinuation. However, hypersensitivity to catecholamines has been observed in patients withdrawn from beta-blocker therapy; exacerbation of angina and, in some cases, myocardial infarction have occurred after *abrupt* discontinuation of such therapy. When discontinuing chronically administered TRANDATE, particularly in patients with ischemic heart disease, the dosage should be gradually reduced over a period of 1 to 2 weeks and the patient should be carefully monitored. If angina markedly worsens or acute coronary insufficiency develops, TRANDATE administration should be reinstituted promptly, at least temporarily, and other measures appropriate for the management of unstable angina should be taken. Patients should be warned against interruption or discontinuation of therapy without the physician's advice. Because coronary artery disease is common and may be unrecognized, it may be prudent not to discontinue TRANDATE therapy abruptly even in patients treated only for hypertension.

Nonallergic Bronchospasm (eg, chronic bronchitis and emphysema): Patients with bronchospastic disease should, in general, not receive beta-blockers. TRANDATE may be used with caution, however, in patients who do not respond to, or cannot tolerate, other antihypertensive agents. It is prudent, if TRANDATE is used, to use the smallest effective dose, so that inhibition of endogenous or exogenous beta-agonists is minimized.

Pheochromocytoma: Labetalol HCl has been shown to be effective in lowering the blood pressure and relieving symptoms in patients with pheochromocytoma. However, paradoxical hypertensive responses have been reported in a few patients with this tumor; therefore, use caution when administering labetalol HCl to patients with pheochromocytoma.

Diabetes Mellitus and Hypoglycemia: Beta-adrenergic blockade may prevent the appearance of premonitory signs and symptoms (eg, tachycardia) of acute hypoglycemia. This is especially important with labile diabetics. Betablockade also reduces the release of insulin in response to hypoglycemia; it may therefore be necessary to adjust the dose of antidiabetic drugs.

Major Surgery: The necessity or desirability of withdrawing beta-blocking therapy prior to major surgery is controversial. Protracted severe hypotension and difficulty in restarting or maintaining a heart beat have been reported with beta-blockers. The effect of labetalol HCl's alpha-adrenergic activity has not been evaluated in this setting.

A synergism between labetalol HCl and halothane anesthesia has been shown (see Drug Interactions under PRECAUTIONS).

PRECAUTIONS: General: ***Impaired Hepatic Function:*** TRANDATE® Tablets should be used with caution in patients with impaired hepatic function since metabolism of the drug may be diminished.

Jaundice or Hepatic Dysfunction: On rare occasions, labetalol HCl has been associated with jaundice (both hepatic and cholestatic). It is therefore recommended that treatment with labetalol HCl be stopped immediately should a patient develop jaundice or laboratory evidence of liver injury. Both have been shown to be reversible on stopping therapy.

Information for Patients: As with all drugs with beta-blocking activity, certain advice to patients being treated with labetalol HCl is warranted. This information is intended to aid in the safe and effective use of this medication. It is not a disclosure of all possible adverse or intended effects. While no incidence of the abrupt withdrawal phenomenon (exacerbation of angina pectoris) has been reported with labetalol HCl, dosing with TRANDATE Tablets should not be interrupted or discontinued without a physician's advice. Patients being treated with TRANDATE Tablets should consult a physician at any sign of impending cardiac failure. Also, transient scalp tingling may occur, usually when treatment with TRANDATE Tablets is initiated (see ADVERSE REACTIONS).

Laboratory Tests: As with any new drug given over prolonged periods, laboratory parameters should be observed over regular intervals. In patients with concomitant illnesses, such as impaired renal function, appropriate tests should be done to monitor these conditions.

Drug Interactions: In one survey, 2.3% of patients taking labetalol HCl in combination with tricyclic antidepressants experienced tremor as compared to 0.7% reported to occur with labetalol HCl alone. The contribution of each of the treatments to this adverse reaction is unknown, but the possibility of a drug interaction cannot be excluded.

Drugs possessing beta-blocking properties can blunt the bronchodilator effect of beta-receptor agonist drugs in patients with bronchospasm; therefore, doses greater than the normal anti-asthmatic dose of beta-agonist bronchodilator drugs may be required.

Cimetidine has been shown to increase the bioavailability of labetalol HCl. Since this could be explained either by enhanced absorption or by an alteration of hepatic metabolism of labetalol HCl, special care should be used in establishing the dose required for blood pressure control in such patients.

Synergism has been shown between halothane anesthesia and intravenously administered labetalol HCl. During controlled hypotensive anesthesia using labetalol HCl in association with halothane, high concentrations (3% or above) of halothane should not be used because the degree of hypotension will be increased and because of the possibility of a large reduction in cardiac output and an increase in central venous pressure. The anesthesiologist should be informed when a patient is receiving labetalol HCl.

Labetalol HCl blunts the reflex tachycardia produced by nitroglycerin without preventing its hypotensive effect. If labetalol HCl is used with nitroglycerin in patients with angina pectoris, additional antihypertensive effects may occur.

Drug/Laboratory Test Interactions: The presence of a metabolite of labetalol in the urine may result in falsely increased levels of urinary catecholamines when measured by a nonspecific trihydroxyindole (THI) reaction. In screening patients suspected of having a pheochromocytoma and being treated with labetalol HCl, specific radioenzymatic or high performance liquid chromatography assay techniques should be used to determine levels of catecholamines or their metabolites.

Carcinogenesis, Mutagenesis, Impairment of Fertility: Long-term oral dosing studies with labetalol HCl for 18 months in mice and for 2 years in rats showed no evidence of carcinogenesis. Studies with labetalol HCl, using dominant lethal assays in rats and mice, and exposing microorganisms according to modified Ames tests, showed no evidence of mutagenesis.

Pregnancy Category C: Teratogenic studies have been performed with labetalol in rats and rabbits at oral doses up to approximately 6 and 4 times the MRHD, respectively. No reproducible evidence of fetal malformations was observed. Increased fetal resorptions were seen in both species at doses approximating the MRHD. There are no adequate and well-controlled studies in pregnant women. Labetalol should be used during pregnancy only if the potential benefit justifies the potential risk to the fetus.

Nonteratogenic Effects: Infants of mothers who were treated with labetalol HCl during pregnancy did not appear to be adversely affected by the drug. Oral administration of labetalol to rats during late gesta- [illegible] doses of 3 to 4 times the MRHD caused a decrease in neonatal survival.

Labor and Delivery: Labetalol HCl given to pregnant women with hypertension did not appear to affect the usual course of labor and delivery.

Nursing Mothers: Small amounts of labetalol (approximately 0.004% of the maternal dose) are excreted in human milk. Caution should be exercised when TRANDATE® (labetalol HCl) Tablets are administered to a nursing woman.

Pediatric Use: Safety and effectiveness in children have not been established.

ADVERSE REACTIONS: Most adverse effects are mild, transient and occur early in the course of treatment. In controlled clinical trials of 3 to 4 months' duration, discontinuation of TRANDATE® Tablets due to one or more adverse effects was required in 7% of all patients. In these same trials, beta-blocker control agents led to discontinuation in 8% to 10% of patients, and a centrally acting alpha-agonist in 30% of patients.

The incidence rates of adverse reactions listed in the following table were derived from multicenter controlled clinical trials, comparing labetalol HCl, placebo, metoprolol and propranolol, over treatment periods of 3 and 4 months. Where the frequency of adverse effects for labetalol HCl and placebo is similar, causal relationship is uncertain. The rates are based on adverse reactions considered probably drug-related by the investigator. If all reports are considered, the rates are somewhat higher (eg, dizziness 20%, nausea 14%, fatigue 11%), but the overall conclusions are unchanged.

The adverse effects were reported spontaneously and are representative of the incidence of adverse effects that may be observed in a properly selected hypertensive patient population, ie, a group excluding patients with bronchospastic disease, overt congestive heart failure, or other contraindications to beta-blocker therapy:

Clinical trials also included studies utilizing daily doses up to 2400 mg in more severely hypertensive patients. Certain of the side effects increased with increasing dose in the entire U.S. therapeutic trials data base for adverse reactions that are clearly or possibly dose-related.

In addition, a number of other less common adverse events have been reported in clinical trials or the literature.

Central and Peripheral Nervous Systems: Paresthesias, most frequently described as scalp tingling. In most cases, it was mild, transient and usually occurred at the beginning of treatment.

Collagen Disorders: Systemic lupus erythematosus; positive antinuclear factor (ANF).

Eyes: Dry eyes.

Immunological System: Antimitochondrial antibodies.

Liver and Biliary System: Cholestasis with or without jaundice.

Musculoskeletal System: Muscle cramps; toxic myopathy.

Respiratory System: Bronchospasm.

Skin and Appendages: Rashes of various types, such as generalized maculopapular; lichenoid; urticarial; bullous lichen planus; psoriaform; facial erythema; Peyronie's disease; reversible alopecia.

Urinary System: Difficulty in micturition, including acute urinary bladder retention.

Following approval for marketing in the United Kingdom, a monitored release survey involving approximately 6,800 patients was conducted for further safety and efficacy evaluation of this product. Results of this survey indicate that the type, severity, and incidence of adverse effects were comparable to those cited above.

Potential Adverse Effects: In addition, other adverse effects not listed above have been reported with other beta-adrenergic blocking agents.

Central Nervous System: Reversible mental depression progressing to catatonia; an acute reversible syndrome characterized by disorientation for time and place, short-term memory loss, emotional lability, slightly clouded sensorium, and decreased performance or neuropsychometrics.

Cardiovascular: Intensification of AV block (see CONTRAINDICATIONS).

Allergic: Fever combined with aching and sore throat; laryngospasm; respiratory distress.

Hematologic: Agranulocytosis; thrombocytopenic or nonthrombocytopenic purpura.

Gastrointestinal: Mesenteric artery thrombosis; ischemic colitis.

The oculomucocutaneous syndrome associated with the beta-blocker practolol has not been reported with labetalol HCl.

Clinical Laboratory Tests: There have been reversible increases of serum transaminases in 4% of patients treated with labetalol HCl and tested, and more rarely, reversible increases in blood urea.

OVERDOSAGE: Overdosage with TRANDATE® (labetalol HCl) Tablets causes excessive hypotension which is posture sensitive, and sometimes, excessive bradycardia. Patients should be laid supine and their legs raised if necessary to improve the blood supply to the brain. The following additional measures should be employed if necessary: **Excessive bradycardia**—administer atropine (3.0 mg). If there is no response to vagal blockade, administer isoproterenol cautiously. **Cardiac failure**—administer a digitalis glycoside and a diuretic. **Hypotension**—administer vasopressors, eg, norepinephrine. There is pharmacological evidence that norepinephrine may be the drug of choice. **Bronchospasm**—administer a $beta_2$-stimulating agent and/or a theophylline preparation.

Gastric lavage or pharmacologically induced emesis (using syrup of ipecac) is useful for removal of the drug shortly after ingestion. Labetalol HCl can be removed from the general circulation by hemodialysis.

The oral LD_{50} value of labetalol HCl in the mouse is approximately 600 mg/kg and in the rat is greater than 2 g/kg. The intravenous LD_{50} in these species is 50 to 60 mg/kg.

DOSAGE AND ADMINISTRATION: DOSAGE MUST BE INDIVIDUALIZED. The recommended *initial* dose is 100 mg *twice* daily whether used alone or added to a diuretic regimen. After 2 or 3 days, using standing blood pressure as an indicator, dosage may be titrated in increments of 100 mg b.i.d. every 2 or 3 days. The usual *maintenance* dosage of labetalol HCl is between 200 and 400 mg *twice* daily.

Since the full antihypertensive effect of labetalol HCl is usually seen within the first 1 to 3 hours of the initial dose or dose increment, the assurance of a lack of an exaggerated hypotensive response can be clinically established in the office setting. The antihypertensive effects of continued dosing can be measured at subsequent visits, approximately 12 hours after a dose, to determine whether further titration is necessary.

Patients with severe hypertension may require from 1200 mg to 2400 mg per day, with or without thiazide diuretics. Should side effects (principally nausea or dizziness) occur with these doses administered b.i.d., the same total daily dose administered t.i.d. may improve tolerability and facilitate further titration. Titration increments should not exceed 200 mg b.i.d.

When a diuretic is added, an additive antihypertensive effect can be expected. In some cases this may necessitate a labetalol HCl dosage adjustment. As with most antihypertensive drugs, optimal dosages of TRANDATE® Tablets are usually lower in patients also receiving a diuretic.

When transferring patients from other antihypertensive drugs, TRANDATE Tablets should be introduced as recommended and the dosage of the existing therapy progressively decreased.

HOW SUPPLIED: TRANDATE® Tablets, 200 mg, white, round, scored, film-coated tablets engraved on one side with "TRANDATE 200 GLAXO," bottles of 100 (NDC 0173-0347-43), bottles of 500 (NDC 0173-0347-44), and unit dose packs of 100 tablets (NDC 0173-0347-47).

TRANDATE Tablets, 300 mg, peach, round, film-coated tablets engraved on one side with "TRANDATE 300 GLAXO," bottles of 100 (NDC 0173-0348-43), bottles of 500 (NDC 0173-0348-44), and unit dose packs of 100 tablets (NDC 0173-0348-47).

TRANDATE Tablets should be stored between 2° and 30°C (36° and 86°F).

TRANDATE Tablets in the unit dose boxes should be protected from excessive moisture.

Drug Treatment of Heart Failure

edited by Jay N. Cohn, MD

0-914316-41-9, approx. 250pp., Oct. '83, $35.00

This volume is aimed at providing clinicians with the physiologic and pharmacologic background necessary to effectively and efficiently create and administer drug therapy regimens for their patients who suffer heart failure. All efforts were made to ensure that the timeliness of each chapter, prepared by internationally respected clinicians and medical scientists, would not be compromised by delays in publication. Consequently, this book presents the very latest thinking on the utilization of drug therapy for heart failure and contains many references as recent as 1982 and 1983. This book is highly recommended to all physicians presently treating patients with heart failure.

TABLE OF CONTENTS AND CONTRIBUTORS

Foreword by Jay N. Cohn, MD

Chapter I
The Treatment of Heart Failure in Perspective: An Overview
by Jay N. Cohn, MD

Chapter II
Pathophysiology of Heart Failure: Deficiency in Cardiac Contraction
by John E. Strobeck, MD, and Edmund H. Sonnenblick, MD

Chapter III
The Role of the Renin—Angiotensin—Aldosterone System in the Pathophysiology of Chronic Heart Failure
by Robert J. Cody, MD, and John H. Laragh, MD

Chapter IV
Pathophysiology of Congestive Heart Failure: The Role of The Kidney
by Norman K. Hollenburg, MD

Chapter V
Congestive Heart Failure: Diagnosis and Principles of Treatment
by Elliot Rapaport, MD

Chapter VI
Conventional Drug Therapy in the Management of Heart Failure
by James E. Doherty, MD

Chapter VII
The Role of Inotropic Agents in the Management of Heart Failure
by Gary S. Francis, MD

Chapter VIII
Vasodilator Therapy of Heart Failure
by Kanu Chatterjee, MB, FRCD

Chapter IX
Captopril in Heart Failure
by William W. Parmley, MD

Chapter X
A Comprehensive Approach to the Treatment of Heart Failure
by Jay N. Cohn, MD

Pattern of Left Ventricular Diastolic Filling in Chronic Aortic Regurgitation: A Gated Blood Pool Assessment

STEVEN J. LAVINE, MD, WILLIAM P. FOLLANSBEE, MD, DAVID P. SHREINER, MD, VENKATARAMAN KRISHNASWAMI, MD, P. S. REDDY, MD, and KAREN S. McKEE

Limited information exists regarding the pattern of left ventricular diastolic filling in moderate to severe chronic aortic regurgitation (AR). The left ventricular diastolic filling curve derived from gated blood pool scans was evaluated in 24 normal subjects and 29 patients with AR. The peak filling rate (PFR), mean filling rate (MFR), peak ejection rate (PER), PFR/MFR, PFR/PER, and the time of the rapid filling period divided by the diastolic time were determined. PFR, MFR and PER were calculated as end-diastolic volumes per second (EDV/s). PFR was lower in the AR group than in the normal subjects (2.24 ± 0.70 vs 3.09 ± 0.71 EDV/s, p <0.001). Similarly, MFR was lower in the AR group (1.31 ± 0.40 vs 1.63 ± 0.29 EDV/s, p <0.01). PER was also reduced in the AR group. Both PFR/MFR and PFR/PER were reduced, while the ratio of rapid filling period to diastolic time was longer in the AR group than in normal subjects. Clinical evidence of congestive heart failure occurred in 8 patients in the AR group. Diastolic filling variables were not significantly different from the asymptomatic subgroup of patients with AR, but were abnormal when compared with those of normal subjects. In patients with AR, an abnormal pattern of diastolic filling was noted, consisting of a reduced PFR, MFR and PFR/PER with a more linear pattern of filling (reduced PFR/MFR) during a longer rapid filling period.

(Am J Cardiol 1985;55:127–132)

Left ventricular (LV) diastolic filling has been described in patients with coronary artery disease,[1–6] systemic hypertension,[7,8] constrictive pericarditis,[9] restrictive[9] and hypertrophic cardiomyopathy[11–13] and valvular heart disease.[5,10,11,14] Specific patterns of diastolic filling have been described for coronary artery disease,[4,8] hypertension,[8] and for mitral and aortic regurgitation.[14] Although diastolic filling of the left ventricle has been extensively described in coronary artery disease, only limited information is available about diastolic filling in chronic aortic regurgitation (AR). The limited data available are conflicting. One study suggested that normal patterns of LV diastolic filling are present in asymptomatic patients, whereas an abnormal and delayed pattern of filling is present in patients with symptoms that suggest congestive heart failure.[14] A second study has noted a reduced peak filling rate (PFR) and a reduced percent stroke volume filled at the time of the PFR in a group of patients with chronic AR awaiting valve replacement.[10] This study evaluates the pattern of diastolic filling in patients with moderate to severe chronic AR using gated blood scintigraphy.

From the Section of Cardiology and Nuclear Medicine, Veterans Administration Medical Center and Presbyterian-University Hospital, University of Pittsburgh, Pittsburgh, Pennsylvania. Manuscript received July 2, 1984; revised manuscript received August 14, 1984, accepted August 20, 1984.

Methods

Patients: We performed gated blood pool scintigrams in 24 patients referred for cardiac catheterization for evaluation of chest pain who had normal coronary arteries with normal LV function (group 1) and in 29 patients with angiographically demonstrated moderate to severe chronic AR (group 2). Of the 29 patients with AR, 21 were asymptomatic and 8 had symptoms of congestive heart failure (dyspnea on exertion, fatigue, orthopnea, and so on). Of the asymptomatic patients, 16 were referred for increasing heart size and 5 for cardiomegaly. Twelve-lead electrocardiograms were performed in all patients. Eighteen of 24 normal patients (75%) and all patients with chronic AR had M-mode and 2-dimensional echocardiograms. All patients with other valvular heart disease, cardiomyopathy, coronary artery disease or coronary artery spasm were excluded.

All group 1 patients with LV hypertrophy were excluded. The presence of LV hypertrophy was assessed by voltage and other electrocardiographic criteria of Romhilt and Estes[15] or by the septal or posterior wall thickness of 12 mm or more on

TABLE I Age, Intervals, Ejection Fraction, Volumes and End-Diastolic Pressure

	Normal (n = 24)	AR (n = 29)
Age (yr)	53 ± 10	51 ± 15
RR (ms)	862 ± 130	871 ± 137
DT (ms)	544 ± 94	555 ± 116
EF (%)	66 ± 7	61 ± 11*
EDV (ml)	154 ± 31	231 ± 46†
SV (ml)	102 ± 16	141 ± 23†
EDP (mm Hg)	8 ± 3	14 ± 7†

* $p < 0.05$; † $p < 0.001$ vs values in normal subjects.
AR = aortic regurgitation; DT = diastolic time; EDP = end-diastolic pressure; EDV = end-diastolic volume; EF = ejection fraction; RR = RR interval; SV = stroke volume.

the M-mode echocardiogram. Normal LV function in group 1 was defined as an ejection fraction greater than 50%, no electrocardiographic evidence of prior myocardial infarction (Q waves longer than 40 ms), the absence of regional wall disease as determined by both contrast ventriculography and gated blood pool scintigraphy, a normal end-diastolic pressure (less than 13 mm Hg), and a normal end-diastolic volume index (<95 ml/m^2). Exercise testing in 18 group 1 patients revealed nondiagnostic electrocardiographic responses in 14, negative responses in 4, and atypical chest pain being induced in 4 patients. Beta- and calcium channel-blocking drugs were discontinued for 72 hours, whereas long-acting nitrates were discontinued 8 hours before cardiac catheterization and gated blood pool scintigraphy in both groups.

Cardiac catheterization: Coronary arteriography, left- and right-sided cardiac catheterization, and contrast left ventriculography, were performed in both groups of patients. Aortic root injection was performed in all patients with chronic AR. AR was graded on a scale of 1 to 4 by 2 independent observers. Agreement occurred in 23 patients. Only 1 observer determined the degree of AR in the other 6 patients. Only patients with grade 3 or 4 (moderate to severe) AR were included in the analysis. Regional wall motion was interpreted as qualitatively normal or abnormal by 2 independent observers. Agreement occurred in all group 1 patients. In group 2 patients, agreement occurred in 26 of 29 patients. Only observer determined regional wall motion in the other 3 patients. In group 2, global hypokinesia was noted in 5 patients and regional wall disease in none.

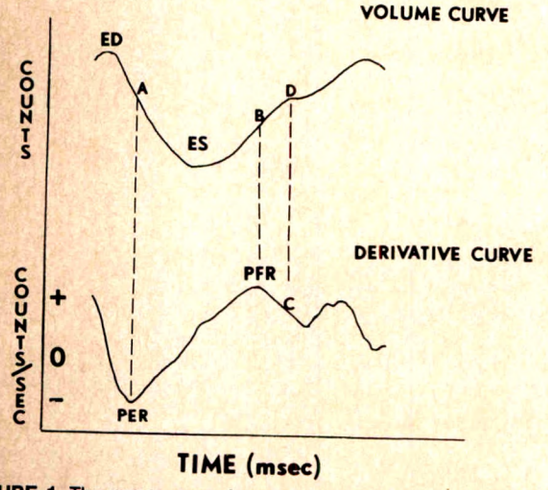

FIGURE 1. The **upper curve** is a representation of a left ventricular volume curve derived from gated blood pool scintigraphy. The **lower curve** is the first derivative of the left ventricular volume curve. Point A is the volume at which the peak ejection rate (PER) occurs. Point B is the volume at which the peak filling rate (PFR) occurs. Point C represents the point on the derivative curve following PFR, which is 20% of PFR. This point is time represents the end of the rapid filling period. The corresponding point in time (D) on the volume curve represents the volume at the end of the rapid filling period. ED = end-diastole; ES = end-systole.

Gated blood pool cardiac scintigraphy: Gated blood pool scintigraphy was performed in the supine position within 4 hours of cardiac catheterization. Before imaging, red blood cells were labeled in vivo with 20 to 25 mCi of technetium-99m. Imaging was performed with a conventional gamma camera and a medium-sensitivity, all-purpose, parallel-hole collimator in the anterior view, in the modified left anterior oblique view that best separated the left from the right ventricle, and in the left lateral view. Image collection was synchronized with the QRS complex of the electrocardiogram by a computer-based electrocardiographic gate (American Optical). A commercial computer system (MDS-A2) divided each cardiac cycle into 32 frames. Images were acquired in a 64 × 64-byte mode matrix for at least 250,000 counts/frame. A plot of the number of cycles collected for each RR interval was inspected. If 99% of the cycles fell within 10% of this average RR interval, then the study was further analyzed (similar to serial mode acquisition with a 10% window). If not, it was excluded because of the likelihood that the rapid filling period may not be accurately represented.[3] Five patients in group 1 and 4 patients in group 2 were excluded.

LV regions of interest were derived for each frame by a semiautomatic second derivative edge-detection algorithm (MUGE) applied to each of the frames. A paraventricular background region of interest was selected by the algorithm. A background subtracted time-activity curve was generated using temporal averaging and spatial smoothing of the image sequence. The resulting curve was subjected to a 5-point smoothing routine. The ejection fraction was calculated from the background subtracted time-activity curve in the standard manner. Regional wall motion was qualitatively assessed as *normal or abnormal* by 2 independent observers for each of the 3 views. Interobserver agreement occurred in 100% of group 1 patients and in 27 of 29 patients in group 2. In group 2, 2 patients produced discordant readings, which were resolved by a single observer. In group 2 patients, global hypokinesia was noted in 5 patients and regional disease in none.

End-diastolic and end-systolic volumes were determined in each patient from the gated blood pool scintigram by a variation of a previously described, count-based, nongeometric method,[16–18] which was validated in our laboratory in 31 other patients. A close correlation was noted between end-diastolic radionuclide volume units and end-diastolic volume by contrast ventriculography (angiographic volume = 4.14 [radionuclide volume units] + 60.1 ml: $r = 0.96$, $p < 0.001$). There was also a close correlation between end-systolic radionuclide volume units and end-systolic volume by contrast ventriculography (angiographic volume = 4.4 [radionuclide volume units] + 19.8 ml: $r = 0.97$, $p < 0.001$). The standard error of estimate was ±19.1 ml for end-diastole and ±16.2 ml for end-systole. End-diastolic and end-systolic radionuclide volume units were calculated for each patient and converted to end-diastolic and end-systolic volume by use of the regression equations noted before. Stroke volume was determined by subtracting end-systolic volume from end-diastolic volume. For the 24 normal subjects and 29 patients with AR, excellent correlations were found with contrast ventriculography for end-diastole ($r = 0.95$) and end-systole ($r = 0.96$).

ABLE II Systolic Ejection and Diastolic Filling Rates

	Normal Subjects (n = 24)	Patients with AR (n = 29)
PER (EDV/s)	4.01 ± 0.88	3.39 ± 0.91*

AR = aortic regurgitation; EDV/s = end-diastolic volumes per second; MFR = mean filling rate; PER = peak ejection rate; PFR = peak filling rate.

TABLE III Diastolic Time Intervals and Percent Filling at These Intervals

	Normal Subjects (n = 24)	Patients with AR (n = 29)
TPER (ms)	107 ± 47	105 ± 34
TPFR/DT	0.33 ± 0.07	0.36 ± 0.16
RFP (ms)	294 ± 52	354 ± 84*
RFP/DT	0.54 ± 0.11	0.64 ± 0.11*
% SV-1/3 DT (%)	46 ± 14	44 ± 13
% SV-PFR (%)	40 ± 11	39 ± 14
% SV-RFP (%)	72 ± 13	75 ± 13

* $p < 0.01$ vs values in normal subjects.
AR = aortic regurgitation; RFP = rapid filling period; RFP/DT = rapid filling period/diastolic time; % SV-1/3 DT (%) = percent stroke volume filled at one-third of diastole; (divided by the RR interval); % SV-PFR = percent stroke volume filled at the time of the peak filling rate; % SV-RFP = percent stroke volume filled at the end of the rapid filling period; TPER = time to peak ejection rate; TPFR/DT = time to peak filling rate/diastolic time.

The time-activity curve is analogous to a plot of volume against time. In Figure 1, end-diastole is the highest part of the upper curve, while end-systole represents the nadir of the curve. The time elapsed from end-systole to the next end-diastole is the diastolic time. The lower curve in Figure 1 is the first derivative of the time-activity curve and is a plot of counts per second vs time. The nadir of the derivative curve represents the peak ejection rate. Point A on the volume curve represents the volume at which the peak ejection rate (PER) occurs. The time elapsed from end-diastole to point A is the time to PER. The maximal value of the first positive deflection on the derivative curve is the PFR. Point B on the volume curve is the volume at which the PFR occurs. The time elapsed from end-systole to point B is the time to PFR and was divided by the diastole time to take into account the effect of heart rate. Point C on the derivative curve represents the time after PFR at which 20% of the PFR occurs and, as noted by Gibson and Brown,[10] represents the end of the rapid filling period. Point D on the volume curve represents the corresponding volume that marks the end of the rapid filling period. The time elapsed from end-systole to point D represents the rapid filling period, which was divided by the diastolic time to take into account the effect of heart rate. This period may not be a precise representation of the rapid filling period because it unavoidably contains the isovolumic relaxation period. The volume filled from end-systole to point D divided by the rapid filling period represents the mean filling rate (MFR) of the rapid filling period. If after PFR, the filling rate did not decrease to exactly 20% of PFR before atrial systole, then the point on the derivative curve that was closest to 20% of the PFR was chosen. The filling rate decreased to less than 30% of the PFR in 49 patients. In each of the 49 patients, diastasis was discernible and corresponded to the first or second point of the diastatic plateau. In the other 4 patients, diastasis (plateau after the rapid filling period) could be clearly identified from the volume curve with complete agreement of 2 independent observers. The first point of diastasis was chosen as the end of the rapid filling period.

The PFR and MFR were expressed as counts per second and divided by end-diastolic counts yielding the PFR or MFR expressed as end-diastolic volumes per second (EDV/s). The percent stroke volume filled at the time of the PFR, at the end of the rapid filling period and at one-third of diastole were measured. Linear interpolation was used to determine the percent stroke volume filled at one-third of diastole if the time of one-third of diastole fell between 2 points on the time-activity curve. This measure was divided by the RR interval due to its high correlation (r = 0.86) with the heart rate.

The ratio PFR/MFR and the ratio of PFR/PER were determined as 2 additional filling indexes. PFR/MFR is an estimate of the linearity of flow during the rapid filling period. A value of 1 indicates a linear flow rate throughout the rapid filling period. The PFR/PER ratio takes into account the known relation between PFR and PER.[5]

Interobserver and intraobserver variability for PFR and MFR were determined in a separate group of 30 subjects: 9 normal subjects, 10 patients with coronary artery disease and normal LV function, and 11 patients with coronary artery disease and abnormal LV function. Interobserver variability was determined by 2 observers independently evaluating and generating the time-activity curve from the left anterior oblique view. The absolute value for interobserver variability was 0.10 ± 0.11 EDV/s for PFR and 0.05 ± 0.05 EDV/s for MFR. Intraobserver variability was determined by 2 separate generations of the time-activity curve by a single observer several weeks apart. The absolute value for intraobserver variability was 0.05 ± 0.05 EDV/s for PFR and 0.02 ± 0.03 EDV/s for MFR.

Statistics: All data are expressed as mean ± standard deviation. Comparison among groups was performed by unpaired *t* tests. When normal subjects were compared to patients with AR with and without heart failure, 1-way analysis of variance was used. If the F statistic was significant at 0.05 level, then *t* tests were used to find where the difference existed. Linear regression was performed to assess the relation between 2 variables.

Results

Table I is a summary of the results of age, RR interval, diastolic time, ejection fraction, end-diastolic volume and pressure, and stroke volume for normal subjects and patients with chronic AR. No significant differences were noted with regard to age, RR interval and diastolic time. The ejection fraction was slightly lower and the end-diastolic volume, stroke volume and end-diastolic pressure were higher in the AR group.

Systolic ejection and diastolic filling rates (Table II): PER, PFR and MFR were reduced in patients with AR. The PFR/PER was also reduced in patients with AR, suggesting that diastolic filling rates were reduced out of proportion to the reduction in PER. The PFR/MFR, an estimate of linearity of flow during the rapid filling period, was reduced in this group.

Diastolic time intervals and percent filling at these intervals (Table III): Of the measurements listed in Table III, only the rapid filling period and the rapid filling period/diastolic time were longer in patients

TABLE IV Ejection Fraction, Volumes, Timing Intervals and Diastolic Filling Measurements

* $p < 0.05$; † $p < 0.001$; ‡ $p < 0.01$; aortic insufficiency without versus aortic insufficiency with congestive heart failure.
CHF = congestive heart failure; other abbreviations as in Tables I to III.

with AR. The reduction in MFR noted earlier was primarily a result of the longer rapid filling period, because the percent stroke volume filled at the end of the rapid filling period was similar in both groups. MFR is equal to the percent stroke volume filled at the end of the rapid filling period divided by the time of the rapid filling period. Figure 2 shows a time-activity curve normalized to end-diastolic counts for a normal patient and a patient with AR. In the patient with AR, diastolic filling appears more linear during a longer rapid filling period, and a reduced PFR is present.

Aortic regurgitation with congestive heart failure vs no congestive heart failure: Table IV is a summary of the results of ejection fraction, ventricular volume, timing intervals and diastolic filling measurements in patients with AR with and without clinical evidence of congestive heart failure. The ejection fraction was lower and the end-diastolic volume and pressure were higher in the AR subgroup with clinical evidence of congestive heart failure. However, diastolic filling values were similar in both AR subgroups. The asymptomatic subgroup still had higher end-diastolic volumes, stroke volumes and end-diastolic pressures than the normal group. PFR, MFR, PFR/MFR and PFR/PER were reduced while the rapid filling period/diastolic time was longer in the asymptomatic AR subgroup than in normal subjects.

Relation between RR interval, ejection fraction and filling indexes: In normal subjects and patients with AR, the average RR interval was unrelated to any filling variable (Table V). In normal subjects, the ejection fraction was related to PFR and MFR as EDV/s and to PFR/PER. In patients with AR, the ejection fraction was only related to PFR and MFR as EDV/s.

Discussion

Using gated blood scintigraphy, we evaluated the pattern of diastolic filling in 24 patients with normal coronary angiograms and 29 patients with moderate to severe chronic AR, 8 of whom had symptoms of congestive heart failure. Patients with moderate to severe chronic AR, as a group, had a slightly lower ejection fraction, but a higher end-diastolic volume, stroke volume and end-diastolic pressure than normal subjects. Diastolic filling was abnormal in patients with AR and was characterized by reduced PFR and MFR, a longer rapid filling period, and more linear rate of filling during the rapid filling period (reduced PFR/MFR). This pattern of diastolic filling is demonstrated in Figure 2 in a patient with severe AR. In our study, PER in the AR group was reduced. Because PFR and PER as EDV/s may be closely related,[5] PFR/PER was used to normalize PFR for PER. The PFR/PER was still reduced in the AR group.

In our group of 29 patients with AR, 8 patients had symptoms suggestive of congestive heart failure. This subgroup had a larger end-diastolic volume, higher

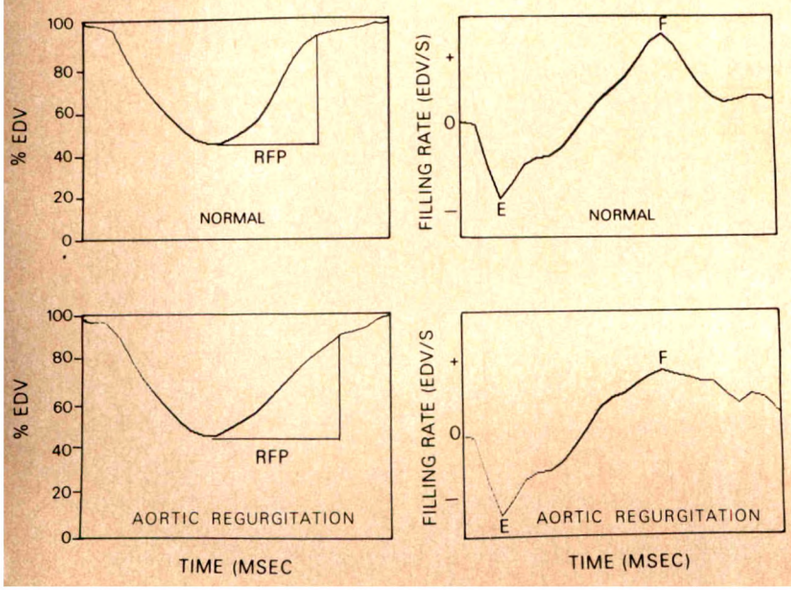

FIGURE 2. Time-activity curves for a normal patient (**top left**) and for a patient with aortic regurgitation (**bottom left**), expressed as percent end-diastolic volume (%EDV). The derivative curves expressed as end-diastolic volumes/second (EDV/s) are shown for both a normal patient (**top right**) and a patient with aortic regurgitation (**bottom right**). The diastolic filling curve is more linear in the patient with aortic regurgitation, with a longer rapid filling period (RFP) (**bottom left**) and a reduced peak filling rate (**bottom right**). E = peak ejection rate; F = peak filling rate.

end-diastolic pressure, and a lower ejection fraction than normal subjects or asymptomatic patients with AR (Table IV). When diastolic filling rates and intervals in the subgroup with coronary artery disease were compared with the asymptomatic subgroup, no significant differences were noted. Thus, the pattern of diastolic filling noted in the subgroup with congestive heart failure was similar, although accentuated, compared with the asymptomatic subgroup. The asymptomatic subgroup continued to demonstrate abnormal diastolic filling compared with normal patients despite the removal of the subgroup with congestive heart failure.

Our data appear to agree with the digitized M-mode findings of Gibson and Brown[10] in that PFR was reduced in patients with chronic AR. However, our data appear to be at variance with the biplane ventriculographic data of Osbakken and Bove.[14] This may be a result of the differing methods of analysis for diastolic filling. Osbakken and Bove[14] divided diastole into tenths and expressed diastolic filling as the percent of end-diastolic volume filled at each tenth of diastole. With regard to their asymptomatic patients, no differences were found at each tenth of diastole compared with normal subjects. However, diastolic filling was linear during diastole in both asymptomatic patients and those with congestive heart failure with AR. A point-by-point comparison throughout diastole should not be entirely relied on because it may not reveal the linearity of the filling curve. In addition, because the ejection fraction was lower in the subgroup with congestive heart failure, it can be anticipated that the percent of end-diastolic volume filled at each tenth of diastole in early diastole would be greater in subgroup with the lower ejection fraction (0% of diastole is equal to 1 minus the ejection fraction). This method of expressing filling is clearly ejection fraction–dependent.

Osbakken and Bove[14] also noted that the MFR of diastole, expressed as EDV/s, was greater in the asymptomatic subgroup of patients with AR. However, we noted a reduced MFR rate of the rapid filling period due to a longer rapid filling period in our comparable subgroup. The MFR of diastole in Osbakken's study was simply the ejection fraction divided by the diastolic filling time. In Osbakken's subgroup, the ejection fraction was slightly, but not significantly, higher and the diastolic filling time was not stated (but expected to be reduced). The elevated MFR of diastole may be a consequence of a higher ejection fraction and a shorter diastolic time. It is too general an index and does not adequately reflect events during the rapid filling period.

Several explanations are possible for the abnormal pattern of diastolic filling in patients with chronic AR. They include abnormal incremental elastance,[19] simultaneous filling from the anterograde mitral flow and retrograde aortic flow and abnormal stiffness.[20–22] Rousseau et al[19] demonstrated abnormal incremental elastance and a reduced velocity of lengthening in patients with chronic AR. Incremental elastance was defined as the change in pressure divided by the change in volume beginning at a common wall stress of 40 kdyne/cm^2 and ending when a 20-ml/m^2 volume increase in the left ventricle occurs. This measurement was made at a time when LV pressure was decreasing and LV volume was increasing. However, abnormal incremental elastance appeared to be confined only to patients with an elevated wall stress or reduced contractility. Because wall stress cannot be determined from radionuclide data, the role of incremental elastance cannot be assessed in our study.

TABLE V Correlation Coefficients Between RR Interval, Ejection Fraction and Filling Indexes

	Normal Subjects (24)		Patients with AR (29)	
	RR	EF	RR	EF

MFR (EDV/s)	−0.12	0.79*	−0.27	0.65*
PFR/MFR	−0.32	−0.05	0.33	−0.03
PFR/PER	0.30	−0.57†	0.13	0.19

* $p < 0.001$ compared with $r = 0$; † $p < 0.01$.
Abbreviations as in Table II.

Another potential explanation for this pattern of diastolic filling may be simultaneous anterograde mitral flow and retrograde aortic flow. Continuous retrograde flow from the aortic root throughout diastole may distort the filling curve producing its linear appearance and lengthened rapid filling period. Because radionuclide techniques cannot quantitate the extent and timing of anterograde mitral flow and retrograde aortic flow separately, the role of diastolic regurgitant flow altering the filling pattern can not be assessed.

Several investigators[20–22] have noted that although the pressure-volume curve is shifted to the right, an abnormal LV chamber stiffness constant may be found in patients with chronic volume overload. However, chamber stiffness is measured at a time of small volume changes and may not reflect early diastolic filling. Furthermore, chamber stiffness constants were found not to correlate with PFRs.[23] Therefore, the role that abnormal LV chamber stiffness plays in patients with chronic AR is not clear.

Clinical implications and limitations of the study: An abnormal pattern of diastolic filling of the left ventricle has been noted in patients with moderate to severe chronic AR with and without symptoms of congestive heart failure. Our data do not allow differentiation of patients with congestive heart failure or more severe AR from those with less severe disease on the basis of the diastolic filling pattern. Further work is needed in describing diastolic filling in patients with varying extents of AR and in patients with heart failure due to chronic AR. Finally, a method of determining the amount, rate and time course of simultaneous aortic regurgitant flow and mitral anterograde flow may be useful in explaining the abnormal pattern of diastolic filling.

Frequency of Mitral Valve Dysfunction from Mitral Anular Calcium as Detected by Doppler Echocardiography

ARTHUR J. LABOVITZ, MD, JEANNE G. NELSON, DENISE M. WINDHORST, HAROLD L. KENNEDY, MD, and GEORGE A. WILLIAMS, MD

Doppler echocardiography is useful for detecting and quantifying mitral regurgitation (MR) and mitral stenosis (MS). To determine the prevalence of these abnormalities in patients with mitral anular calcium (MAC), 51 consecutive patients who had an echocardiographic diagnosis of MAC were examined by Doppler ultrasound. Transmitral flow was evaluated to determine the presence of MR or left ventricular inflow obstruction (MS) by continuous and pulsed-wave Doppler echocardiography. The severity of these hemodynamic abnormalities was quantitated by previously described techniques. Eleven patients (22%) had mild MR, 17 (33%) had moderate to severe MR and 4 (8%) had significant MS. Clinical findings such as a systolic murmur, evidence of congestive heart failure, and dyspnea on exertion were not helpful in distinguishing patients with no or mild MR from those who had moderate to severe MR. M-mode measured left atrial size was significantly larger ($p < 0.05$) in patients with moderate to severe MR. This study suggests that MR is often associated with MAC, that MS is not a rare finding with MAC, and that Doppler echocardiography can quantitate these lesions in the elderly when symptoms are not specific and physical findings are inconclusive or absent.

(Am J Cardiol 1985;55:133–137)

Mitral anular calcium (MAC) is a frequent finding in elderly persons.[1–8] Autopsy studies performed in persons older than 50 years reveal that the prevalence is 10 to 15%, depending on age and gender.[9–13] Although radiologists have long recognized the characteristic C- or J-shaped opacity in the posterior-inferior portion of the cardiac silhouette on chest x-ray, only since the advent of echocardiography have clinicians recognized the frequency of this entity. Efforts to accurately assess the incidence of both mitral regurgitation (MR) and functional mitral stenosis (MS) in patients with MAC have been handicapped by the lack of invasive hemodynamic studies in large numbers of these patients, many of whom are elderly and not sufficiently symptomatic to warrant cardiac catheterization. Recent developments in Doppler technology have allowed us to evaluate noninvasively whether MAC has hemodynamic significance.[14–19] We evaluated the prevalence of MR and MS in a consecutive series of patients with MAC and correlated Doppler findings with standard echocardiographic and clinical characteristics.

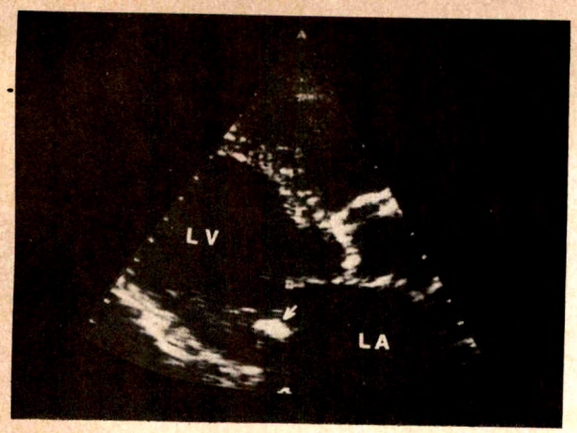
Methods

Patients: The patient population consisted of 51 consecutive patients (30 women, 21 men) with an echocardiographic diagnosis of MAC. They were 54 to 91 years old (mean 70). Patients with calcified mitral valve leaflets were excluded. Most patients were referred for symptoms of chest pain, congestive heart failure, dyspnea or evaluation of a cardiac murmur. Ten patients had hypertension, 7 had coronary artery disease, 4 had had aortic valve replacement, 2 patients had aortic stenosis, 1 patient had cardiomyopathy, and 3 had chronic renal failure. The other patients had no associated detectable cardiovascular abnormalities. The frequency of associated cardiovascular abnormalities were similar in patients with and those without MR.

Echocardiographic studies: M-mode and 2-dimensional (2-D) echocardiography and cardiac Doppler studies were performed using an Irex System IIIB. This phased-array imaging system uses a 2.5-MHz transducer for M-mode and 2-D echocardiography. MAC was diagnosed by echocardiographic findings (Fig. 1) using standard criteria.[1,2,4,20] Measurements of left atrial size were determined from the M-mode study according to recommendations of the American Society of Echocardiography.

Doppler studies: The Doppler unit uses a frequency of 2.0 MHz and can be operated either in a pulsed or continuous-wave mode. In the pulsed mode the sample volume is 7 mm in diameter and can be located at various depths between 0 and 13 cm, the location of which is indicated by a box displayed along the Doppler cursor. The maximal velocity limit



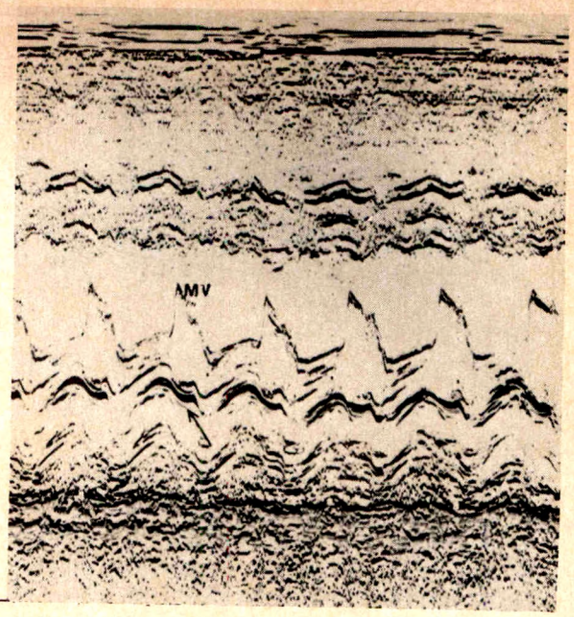


FIGURE 1. M-mode and 2-dimensional echocardiogram from a patient with posterior mitral anular calcification (**arrows**). Bright echoes are seen anterior to the left ventricular posterior wall and move parallel to this structure. LA = left atrium; LV = left ventricle; MV = mitral valve.

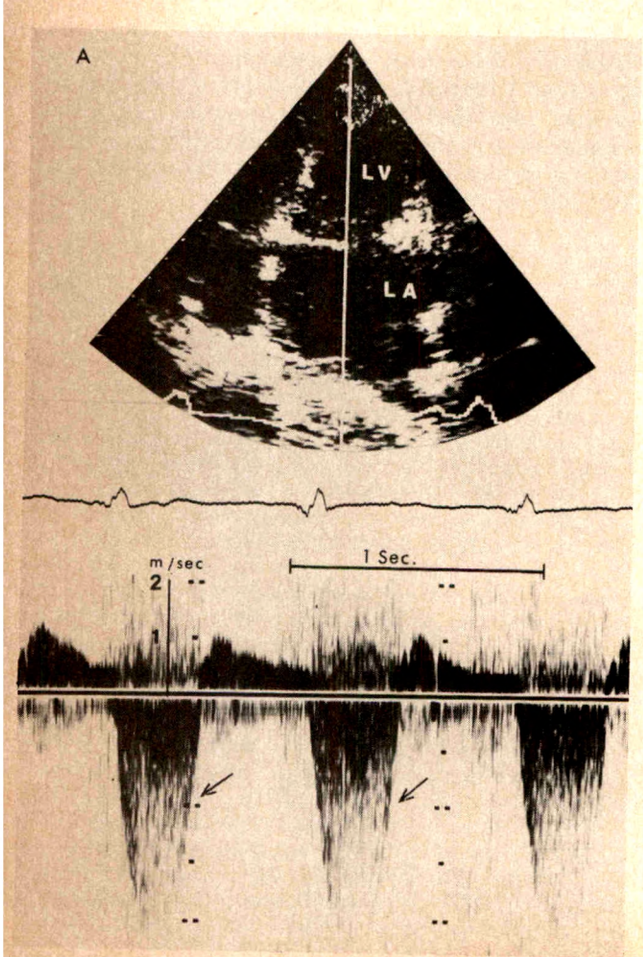

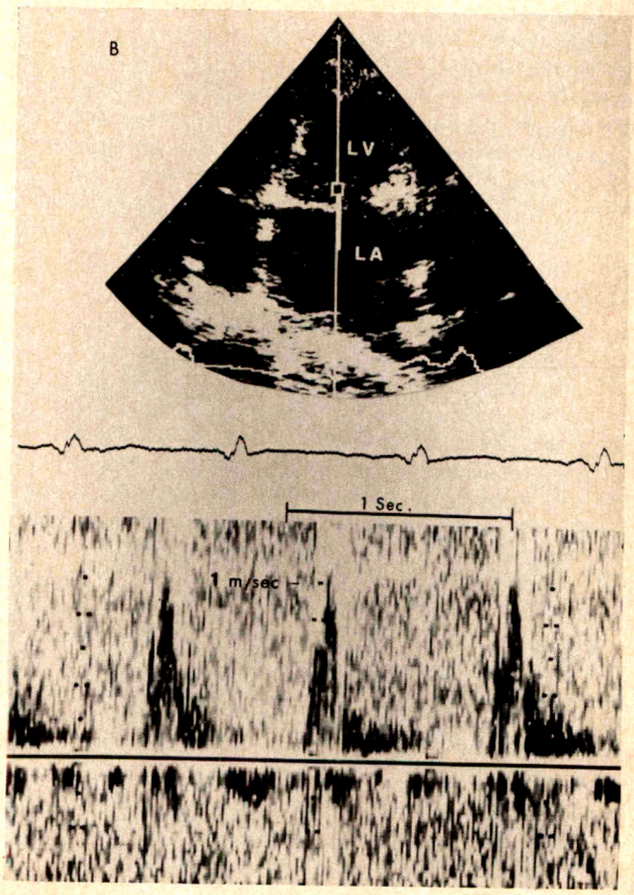

FIGURE 2. Mapping technique for quantitating mitral regurgitation. **A**, with the transducer located at the cardiac apex, transmitral flow is sampled in the continuous mode. **Arrow** indicates high-velocity systolic jet of mitral regurgitation. Forward diastolic flow is recorded above the baseline. Transmitral flow is then sampled in the pulsed mode with the sample volume (as indicated by **box** on the 2-dimensional image) positioned at the mitral valve level (**B**) and at various depths in the left atrium (LA) (**C** and **D**, on opposite page) to sample for regurgitant flow (**arrows**), which is recorded during systole below the baseline. Regurgitant flow detected more than 2 cm behind the mitral valve was graded moderate to severe. This patient has moderate to severe mitral regurgitation. Note the marked left atrial enlargement. LV = left ventricle.

using a baseline offset is 3.4 m/s at depths of less than 8 cm and 2.2 m/s at depths of 8 to 13 cm. The continuous-wave Doppler mode permits recording of velocities of up to 6 m/s, although range resolution is no longer possible as Doppler shifts are detected along the entire Doppler beam. The blood flow velocities can then be displayed graphically as a spectral analysis on hard copy, with the gray scale of the spectral analysis proportional to the number of red blood cells moving at any given velocity.

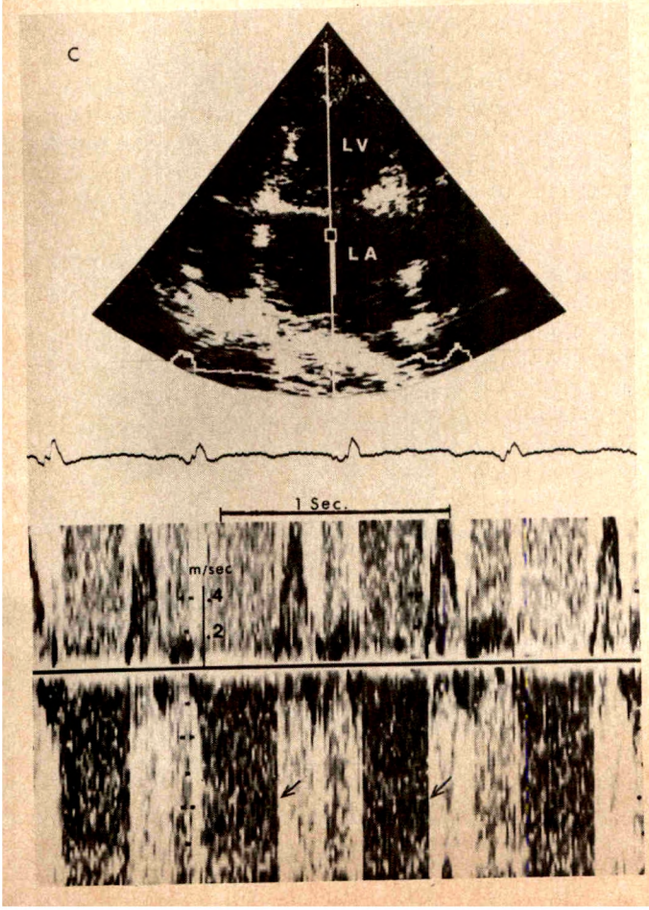
Transmitral flow was sampled by placing the transducer at the cardiac apex and aligning the Doppler cursor parallel to flow using the 2-D image from the 4-chamber view. The valve was routinely scanned first in the continuous mode to determine maximal velocities of left ventricular inflow as well as to detect the presence of MR. MR was defined as a holosystolic jet moving away from the transducer with velocity of more than 2 m/s. If MR was present, it was quantitated in the pulsed mode and the extent of the regurgitant jet was mapped in the left atrium. For the purposes of this study, systolic flow away from the transducer seen 2 cm or more into the left atrium was considered significant (moderate to severe) MR (Fig. 2). Jets that were less than 2 cm into the left atrium were considered mild MR. The mitral valve orifice area was determined by the pressure half-time method[14]; valve areas less than 2 cm^2 were classified as functional MS (Fig. 3).

Patient groups: The patients were separated into 4 groups on the basis of Doppler findings. Group I consisted of patients with essentially normal mitral flow dynamics and no evidence of MS or MR, group II of patients with mild MR, group III of patients with moderate-to-severe MR, group IV consisted of patients with obstruction to left ventricular inflow (MS).

Statistical analysis: To compare echocardiographic and Doppler variables among the 4 groups, a 1-way analysis of variance was used. Intergroup analyses were performed using a Tukey's test. Chi-square analysis was used to determine significant differences ($p < 0.05$) between clinical characteristics in patients with and those without significant MR.

Results

Clinical characteristics: Of the 51 patients, 28 (55%) had MR diagnosed by Doppler. Of these 28 patients, an apical systolic murmur was heard in only 17 (61%). Of the 17 patients found to have moderate to severe MR by Doppler, only 65% had a murmur consistent with MR. Eleven of the 23 patients without evidence of MR by Doppler had a systolic murmur. An apical systolic murmur, therefore, had limited predictive value in screening patients with MAC for MR. When the patients with minimal or no MR (groups I and II) were compared to those with moderate to severe MR (group III), no statistically significant differences in symptoms and clinical findings were noted; however, a systolic murmur, dyspnea and a history of congestive heart failure were found more frequently in the patients who had moderate to severe MR (Table I). Of the 4 patients found to have MS by Doppler echocardiography, none had a diastolic rumble or opening snap, 2 had a systolic ejection murmur loudest at the left sternal



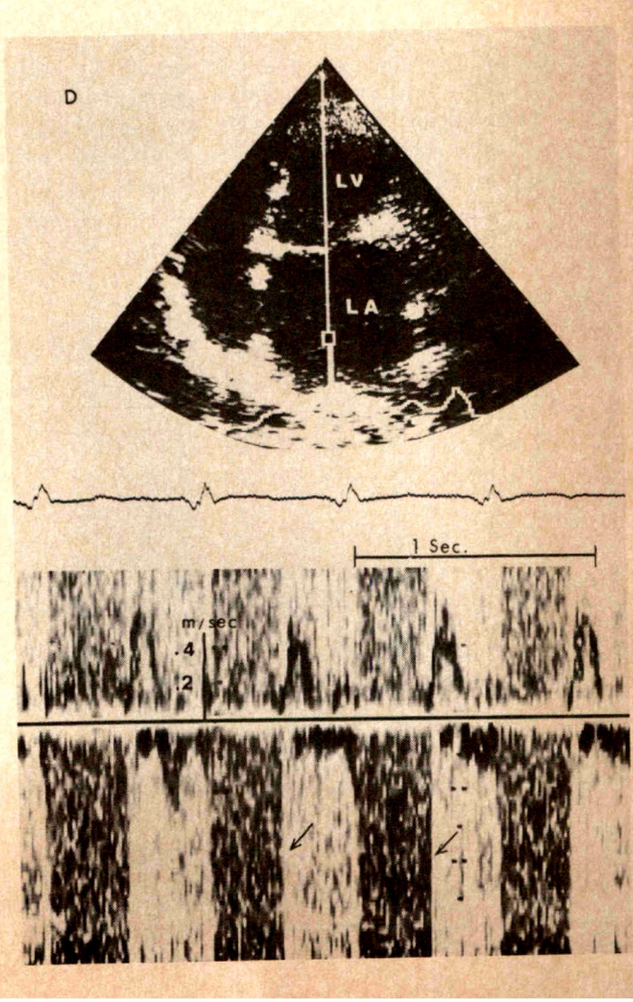


TABLE I Clinical Characteristics of Patients with Doppler Quantitated Mitral Regurgitation

	No or Mild MR Groups I and II	Moderate to Severe MR Group III	p
n	30	17	...

CAD = coronary artery disease; CHF = congestive heart failure; MR = mitral regurgitation; NS = not significant.

border, 3 had symptoms of congestive heart failure, and 1 was status post–cardiac arrest.

Echocardiographic and Doppler studies: The 51 patients were classified into 4 groups on the basis of Doppler examination. Group I included 19 patients (37%) who had no MR or MS, group II included 11 patients (22%) who had mild MR, group III included 17 patients (33%) who had moderate to severe MR, and group IV included 4 patients (8%) who had functional obstruction to left ventricular inflow (MS).

A statistical analysis of echocardiographic and Doppler parameters in the 4 groups is illustrated in Table II. The patients with moderate to severe MR (group III) had a significantly larger mean left atrial size (4.95 ± 0.74 cm) compared with group I (4.18 ± 0.75 cm) and group II (4.28 ± 0.44 cm). There was no statistically significant difference in left atrial size between patients with minimal or absent MR. Peak velocity of left ventricular filling was significantly higher in group IV patients (1.75 ± 0.33) than in group I (1.21 ± 0.28), group II (1.38 ± 0.35) and group III (1.21 ± 0.25) patients. The mitral valve orifice as measured by the Doppler pressure half-time method was significantly smaller in patients with MS (group IV) (1.67 ± 0.26) compared to group I (3.10 ± 0.64), group II (3.35 ± 1.15) and group III (3.18 ± 0.72). Therefore, significant left atrial enlargement in a patient with normal left ventricular inflow velocities and relatively normal mitral valve orifice was a good predictor of moderate to severe MR.

Functional mitral stenosis: Four patients had Doppler-defined MS. Two of these 4 patients underwent right- and left-sided cardiac catheterization, at which time obstruction to left ventricular inflow was confirmed. The clinical and laboratory characteristics of these patients are listed in Table III. In general, these 4 patients had much denser MAC and 3 of the 4 had anterior as well as posterior anular calcification seen on echocardiography. All 4 patients had evidence of at least some calcification of the aortic root and valve while 2 patients were believed to have hemodynamically significant aortic stenosis. All 4 patients had symptoms referable to the cardiovascular system.

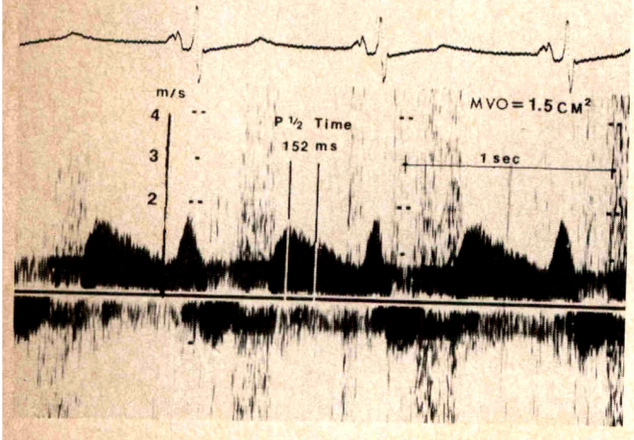

FIGURE 3. Pressure (P) half-time technique for calculation of mitral valve orifice (MVO). The pressure half-time is the time required for the pressure gradient to fall to half its peak value. Because of the squared relation between velocity and gradient, this is the time required for the peak velocity to decrease to a value equal to the peak velocity divided by the square root of 2. An estimate of mitral valve orifice is then obtained by dividing 220 ms by this number. In this patient, mitral valve orifice equals 220/152 or 1.5 cm^2.

Discussion

In 1962, Korn et al[21] reported a morphologic study of 14 patients with massive MAC where they found a complete rigid ring of calcification 1 to 3 cm in diameter in the region of the mitral anulus. In 9 of the 14 patients a significant degree of stenosis, as judged by visual inspection, was present in the absence of leaflet disease. Since then, other investigators[22–24] have reported invasive hemodynamic confirmation of such lesions at cardiac catheterization. In all cases, physical findings suggestive of MS were lacking. However, no consecutive series estimating the incidence of left ventricular inflow obstruction in patients with MAC has been reported because of the lack of a sensitive noninvasive method to describe this phenomena.

Doppler ultrasound provides good correlation when compared with invasive technique and 2-dimensional echocardiography in estimation of mitral valve orifice when the pressure half-time technique reported by Hatle et al is applied.[14,15,25] Since this technique depends on flow dynamics between left atrium and left ventricle, one would expect this relation to accurately reflect valve orifice in the presence of subvalvular and valvular stenosis.

Several investigators have examined the usefulness of Doppler in the evaluation of MR.[16–19] The specificity of this technique ranged from 89 to 100% and the sensitivity was 90% or greater compared with angiography. Mild cases of MR at left ventriculography are frequently missed by Doppler. Using a mapping technique similar to that used in the present study, Abbasi et al[16] showed a high correlation (r = 0.88) compared to ventriculography when assessing the degree of regurgitation.

MAC is frequently believed to be a benign degenerative process that affects the elderly. However, in the present study, 33% of the patients with MAC had valvular insufficiency of hemodynamic importance as graded by Doppler. In addition, a few patients have

HSM = holosystolic murmur; MV = mitral valve; SEM = systolic ejection murmur.

functional MS even after patients with abnormally thickened or calcified mitral valve leaflets were excluded from consideration.

Although patients referred for echocardiographic examination represent a select group, the demographic features of our study patients are similar with respect to age, physical findings and symptoms compared with other series selected by echocardiographic, roentgenographically or autopsy proved MAC.[3,9–11,13] A systolic murmur heard at the left sternal border or apex has been reported in 35 to 100%[7,9,10,12,13] of patients with MAC, compared with approximately 60% in the present study. However, MR is not believed to be the cause of this murmur in all of these patients.[7,8,10,20] Other explanations for the murmur include the vibration of the mitral valve ring itself or systolic ejection murmurs transmitted from a sclerotic aortic root.[10–12] Decreased mobility of the mitral valve and chordae as well as loss of the normal systolic "sphincter" action of the mitral ring are believed to be responsible for the valvular insufficiency. Simon and Liu[10] suggest from their report of 59 postmortem examinations of cases of MAC that significant MR is a common occurrence in the presence of this lesion. Mellino et al[8] found MR in 10 of 24 (42%) patients with MAC undergoing cardiac catheterization.

Mitral Valve Prolapse and Ruptured Chordae Tendineae

ROBERT M. JERESATY, MD, JESSE E. EDWARDS, MD,
and SURENDRA K. CHAWLA, MD

To determine the causes of ruptured chordae tendineae and a suspected etiologic role for mitral valve prolapse (MVP), the mitral valve in 25 consecutive and surgically proved cases of chordal rupture were examined. The diagnosis of MVP was made on the basis of redundancy and marked hooding of the mitral leaflets and on histologic changes. MVP was the underlying morphologic abnormality in 23 patients, only 1 of whom had infective endocarditis that was responsible for the rupture. Thus MVP was the only underlying morphologic abnormality in 22 of 25 patients (88%). Another finding in this study was the demonstration of auscultatory and angiographic or echocardiographic evidence of MVP in 4 patients, aged 4 to 11 years (mean 7), before chordal rupture; no patient had had endocarditis. The morphologic and historical evidence would indicate that MVP is probably the most common cause of so-called spontaneous chordal rupture.

(Am J Cardiol 1985;55:138–142)

Mitral valve prolapse (MVP) generates considerable interest in view of its prevalence, its variable symptoms, its auscultatory findings and its complications.[1–3] Some investigators believe that this syndrome is the underlying cause of ruptured chordae tendineae of the mitral valve[3–8]; others do not.[9–11] To determine the causes of ruptured chordae tendineae and a suspected etiologic role for MVP, we examined the mitral valve and reviewed clinical, echocardiographic and cineangiographic findings in 25 consecutive cases of surgically proved chordal rupture. In 4 of the patients, MVP had been documented 4 to 11 years earlier, adding further support to the suspected causal relation.

Methods

The surgical pathologic series: In addition to gross examination by the cardiac surgeon, the cardiologist and the Pathology Department at Saint Francis Hospital and Medical Center, 20 of the 25 valves were examined by one of us, 2 by the Department of Pathology at Brigham and Womens Hospital in Boston, and 1 by William C. Roberts in Bethesda. To distinguish ruptured chordae tendineae from chordae that had been cut during the surgical procedure, the pathologist was aided by the surgeon's having placed a metal clip across the base of chordae that had been found ruptured at operation. All of our 25 patients, except 1 who underwent surgery in July 1977, underwent mitral valve replacement for severe mitral regurgitation (23 at Saint Francis Hospital and Medical Center and 2 elsewhere) during a 4½ year period starting in June 1978.

The diagnosis of MVP was made on the basis of the following findings[7,12,13]: (1) large, redundant leaflets; (2) marked interchordal hooding involving at least half of the anterior leaflet or at least two-thirds of the posterior leaflets; (3) large mitral anulus, seen in 15 of 25 of our cases, which was larger than 10.5 cm (the upper limit of normal[13]) (mean 12.7, range 10.5 to 16.5); and (4) microscopic evidence of myxomatous changes in the form of thickening of the spongiosa invading and focally interrupting the fibrosa.

Documentation of mitral valve prolapse before chordal rupture—4 patients: In 4 patients, the diagnosis of MVP was made before the occurrence of chordal rupture. The clinical diagnosis of MVP was made on the basis of a nonejection click often associated with a late systolic murmur.[1–3] The M-mode echocardiographic and angiographic criteria were those previously described.[3] The M-mode criteria for ruptured chordae tendineae were those summarized by Child et al[14] and the 2-dimensional echocardiographic criteria were those described by Mintz et al.[15]

Results

Clinical, echocardiographic, hemodynamic and angiographic data: Of the 25 patients with surgically proved ruptured chordae tendineae, 16 were men and 9 were women, aged 28 to 84 years (mean 61). Only 1 patient gave a history of rheumatic fever. A systolic murmur was noted 3 to 45 years before surgery in 21 of the 23 patients in whom information on previous murmurs was available; in 1 patient, no murmur was heard before recent deterioration, during which a loud pan-

From the Section of Cardiology, Department of Medicine, Saint Francis Hospital and Medical Center, Hartford, Connecticut. Manuscript received June 11, 1984; revised manuscript received August 31, 1984, accepted September 4, 1984.

Address for reprints: Robert M. Jeresaty, MD, Director, Section of Cardiology, Saint Francis Hospital and Medical Center, 114 Woodland Street, Hartford, Connecticut 06105.

systolic murmur was noted, and in another patient, no murmur was noted 3 years before recent deterioration. Information on the type of murmur was usually lacking. However, in 5 patients, including 1 who had endocarditis, the murmur was late systolic and preceded by a click in 3, and in 5 other patients the murmur was pansystolic. In all 25 patients, a pansystolic murmur was heard before mitral valve replacement.

A history of sudden clinical deterioration was obtained in 15 patients and in the remaining patients, heart failure was insidious in its onset and in its course. As will be mentioned later, there was a history of endocarditis in only 3 patients, and in 2 of these, endocarditis was believed to be responsible for the chordal rupture.

An M-mode echocardiogram of good quality was available for our review in 20 patients. Coarse diastolic fluttering of the posterior leaflet, which was observed in 12 patients, was the most common finding. Systolic echoes in the left atrium were noted in 9 patients and systolic fluttering of the mitral valve in 5. A 2-dimensional echocardiogram was available in only 5 patients, confirming the M-mode diagnosis of ruptured chordae tendineae without providing additional diagnostic information.

The pulmonary artery wedge pressure tracing showed a prominent "v" wave in 18 of our patients. Cine left ventriculography showed severe mitral insufficiency in all patients with evidence of MVP in 21. Aortic insufficiency was found in 2. Coronary arteriography, which was performed in 23, was normal in 17 and showed coronary artery disease in 6 (1-vessel disease with 70% or less stenosis in 4 and 2-vessel disease in 2).

Mitral valve replacement with a porcine heterograft was carried out in all patients, aortic valve replacement in 2, closure of an atrial septal defect in 1 patient and coronary artery bypass surgery in 5. Only 1 patient died postoperatively.

Pathologic findings: MVP was the underlying pathologic abnormality in 23 patients (15 men and 8 women), bacterial endocarditis in the absence of MVP in 1 patient with tetralogy of Fallot, and the cause of the mitral valve disease was not evident in an 81-year-old woman. Of the 23 patients with underlying MVP, 2 have had endocarditis that could be held historically and pathologically responsible for the rupture in only 1 patient; in the other patient, a pansystolic murmur had been heard and an M-mode echocardiogram had shown evidence of chordal rupture before the occurrence of endocarditis. Thus, in our series, endocarditis occurred in 3 patients, including 2 with MVP, but was the cause of rupture in only 2. Excluding these 2 patients and the patient in whom MVP was not noted and the underlying pathology had not been defined, MVP was the only underlying pathologic abnormality in 22 of our 25 patients (88%) who had ruptured chordae tendineae (Table I).

TABLE I Cause of Ruptured Chordae in 25 Patients

MVP without endocarditis	22 (88%)
MVP with endocarditis	1 (4%)
Endocarditis without MVP	1 (4%)
Undetermined	1 (4%)

MVP = mitral valve prolapse.

The ruptured chordae were those of the posterior leaflet in 13 patients (52%), of the anterior leaflet in 10 (40%) and of both in 2 (8%). Of the chordae attached to the posterior leaflet, those of the middle scallop were the most commonly ruptured (11 of 13). In all of our patients, the characteristic hooding was not limited to the segment of the valve attached to the ruptured chordae.

The typical gross specimen was a valve that had been removed in 1 piece and opened at or near 1 of the commissures. In an occasional case, continuity of the valvular elements had been retained so that the orifice was intact (Fig. 1). In all specimens, there were varying degrees of interchordal hooding (Fig. 2). In no instances was there evidence of commissural fusion.

In all cases, histologic examination revealed that there were some signs characteristic of the myxomatous mitral valve. Among the chords that had ruptured, changes varied. The most consistent change was loss of clear, collagenous staining with the van Gieson counterstain done on sections stained primarily for elastic tissue. In some, there was a fragmentation of the distal end with little fibrous reaction. Occasionally a fibrous reaction

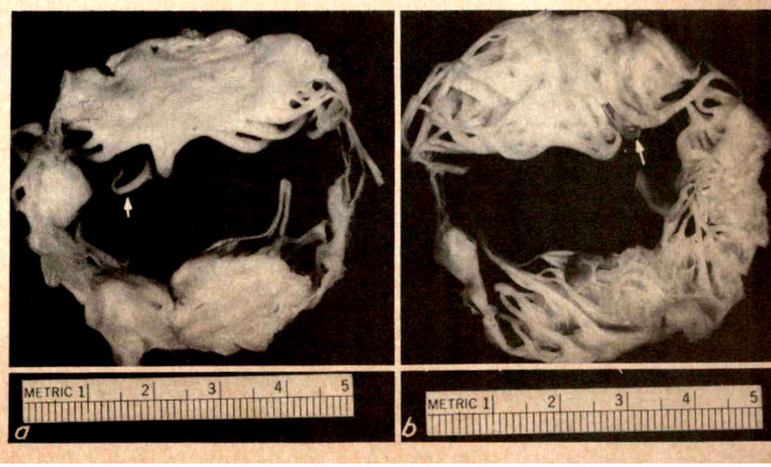

FIGURE 1. (R-79-160, case 6, male, age 51 years). Continuity of valvular elements has been maintained. **a,** valve viewed from atrial aspect. Anterior leaflet in **upper** part of photograph. Valvular elements vary in thickness. Greatest opacity in anterior leaflets of which inserting chordae had ruptures as shown in **b. b,** ventricular aspect of valve. Metal clip across base of ruptured chordae which inserts into anterior leaflet (**arrows**).

TABLE II Mitral Valve Prolapse Diagnosed Before Chordal Rupture in 4 Patients (Mean 7 Years)

No. of Pts.	Findings
2	MSC, LSM No echo or cine
1	MSC, LSM Positive cine
1	LSM Positive echo & cine

LSM = late systolic murmur; MSC = midsystolic click.

occurred at the distal end imparting a knobby thickening at the extremity.

Mitral valve prolapse documented before chordal rupture: subseries of 4 patients (Table II): In 4 patients, MVP was documented 4 to 11 years (mean 7) before chordal rupture, which was associated with clinical deterioration and a new pansystolic murmur. No patient had had endocarditis. In 3 of these patients, a midsystolic click followed by a late systolic murmur had been heard and the cine left ventriculogram, which was performed in 1, had been positive for MVP. The phonocardiogram of 1 of these 3 patients, which has been previously published,[3] showed a midsystolic click followed by a late systolic murmur with subsequent development of a new pansystolic murmur associated with acute heart failure; suspected MVP and chordal rupture were subsequently confirmed at surgery. The fourth patient had a late systolic murmur and a positive echocardiogram and cineangiogram in 1971 (Fig. 3); his chordal rupture occurred probably while he was chopping wood in 1979. His preoperative phonocardiogram, echocardiogram and cine left ventriculogram are shown in Figure 4 and his mitral valve is shown in Figure 1.

Discussion

MVP has been recognized during the past 2 decades as the most prevalent mitral valve disorder and the most frequent cause of chronic pure mitral insufficiency.[3,8,13] Although the association of MVP and chordal rupture has been frequently reported, the etiologic link between them has been refuted by some workers[9–11] but recognized or postulated by others.[3–8] The first report of ruptured chordae associated with probable MVP appeared in 1966.[16] Despite this report, the cause of ruptured chordae tendineae has been ascribed by most investigators to other diseases[10,17,18] and most cases have been labeled as "idiopathic."[10] In 1972, Selzer et al[9] stated that "etiologically there is no relationship or overlap between isolated rupture of chordae tendineae and 'the billowing mitral leaflet syndrome.' " He also stated in another report[10] that the most common cause of rupture of chordae tendineae in the course of MVP is infective endocarditis and that spontaneous rupture of chordae tendineae in milder cases of MVP is "unproven and doubtful." He cited several arguments against a causal association between MVP and chordal rupture: (1) Ruptured chordae usually affects males over the age of 45 years. (2) The holosystolic murmur appears abruptly and is not preceded by clinical findings of prolapsing mitral valve. (3) Rupture of chordae tendineae in a patient with MVP is rare and in many

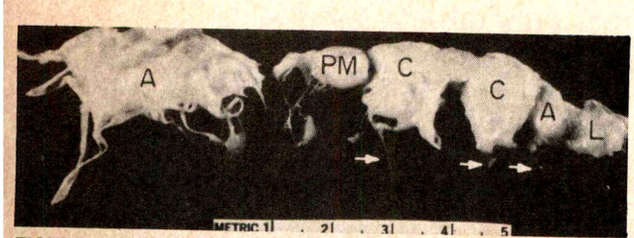

FIGURE 2. (R-80-251, case 3, female, age 66 years). A case in which continuity of valvular tissue had been divided. The anterior (A) leaflet shows relatively little change. The 3 scallops of the posterior leaflet are prominent. Each scallop of the posterior leaflet displays prolapse or hooding, whereas the central of the scallops is bifid. Chordae to central and anterolateral scallops had ruptured (**arrows**). AL = anterolateral scallop; C = central scallop; PM = posteromedial scallop.

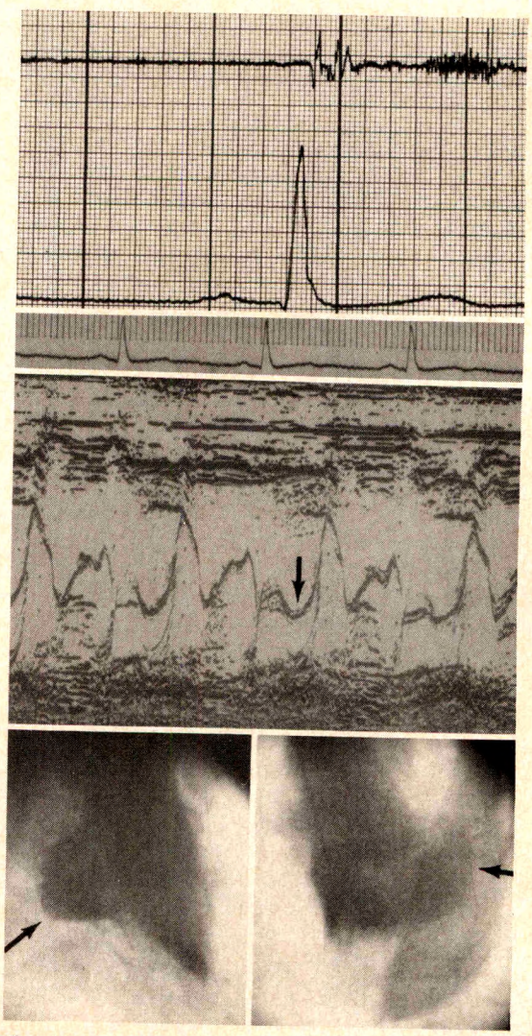

FIGURE 3. Case 6. Phonocardiogram, echocardiogram and cine left ventriculogram documenting MVP in 1971 in a 51-year-old man who had ruptured chordae tendineae while chopping wood in 1979 (see Figure 4 for same studies after chordal rupture and Figure 1 for pathologic documentation of MVP and chordal rupture). Reproduced with permission of Raven Press from Jeresaty.[3]

cases can be traced to endocarditis rather than being spontaneous. (4) The areas of the mitral valve detached from the chordae may show myxomatous changes, but these changes are secondary and are related to the trauma of turbulent flow, the remainder of the cusp being normal.

These well formulated and cogent arguments have influenced us in the design of our study. We examined 25 consecutive patients, looking for historical and pathologic evidence of endocarditis as the cause of rupture and seeking evidence of a primary MVP as a possible etiologic mechanism of the rupture. Furthermore, we reviewed the physical and echocardiographic findings in 4 patients with surgically proved chordal rupture who had been evaluated by us a mean of 7 years earlier.

We concur with Selzer that despite the preponderance of MVP in women, most patients with ruptured chordae tendineae are men older than age 45 years (15 of our 25 patients, 60%). This finding may simply indicate that men with MVP are at a higher risk of having ruptured chordae tendineae as they are of having progressive mitral insufficiency.

One of the major findings of our study was the clinical demonstration of MVP in 4 patients who, in the absence of endocarditis, subsequently had ruptured chordae tendineae (Table II). These 4 patients, when added to 11 others with previously documented MVP[5,11,19–25] (midsystolic and late systolic murmur in 8, isolated late systolic murmur in 3 with a positive echocardiogram in 2) and subsequent chordal rupture in the absence of endocarditis, provide a strong argument in favor of a causal relation between MVP and ruptured chordae tendineae. In most patients with ruptured chordae tendineae, a preceding click and a soft late systolic murmur may have been overlooked by physicians who, before 1960, considered these findings to be extracardiac.[3,11] It is also possible that no adequate auscultation was performed and no echocardiogram was obtained before the appearance of a pansystolic murmur of chordal rupture.[11]

In our series, MVP was the underlying pathologic abnormality in 23 patients (92%), endocarditis in the absence of MVP in 1 patient, and the valvular abnormality was unknown in 1 patient. Of the 23 patients with underlying MVP, 2 have had endocarditis, but it is only in 1 patient that endocarditis could be held historically and pathologically responsible for the chordal rupture. Therefore, our series demonstrates that MVP, per se, is the underlying cause of ruptured chordae tendineae in 88% of our patients and that endocarditis is responsible for only 8%, including only 4% of chordal rupture in patients with MVP (Table I), Selzer's statement notwithstanding.[10] An association of MVP and proved myxomatous mitral valve (necropsy or surgery) has also been reported.[3,11,13,19,21,22,24–31]

Demonstration in our series and in others[6,7] of gross and histologic changes of MVP in parts of the mitral valve not involved in chordal rupture adds further confirmation to the postulated causal link between MVP and rupture. Moreover, friction lesions of the left ventricular endocardium frequently noted in idiopathic MVP have been observed in relation to the chordae that have ruptured, lending support to the concept that the usual features of MVP existed before the event of chordal rupture.[6]

Rupture of chordae to the anterior leaflet is not uncommon; it occurred in 12 of our patients, including 2 with additional posterior leaflet rupture. The clinical picture of these patients was indistinguishable from those with ruptured chordae to the posterior leaflet. When the posterior leaflet was involved, the chordae to the middle scallop were the most frequently affected (11 of 13 patients).[32] Unlike Waller et al,[13] we have noted a large mitral anulus in most of our patients with MVP and ruptured chordae tendineae (15 of 23).

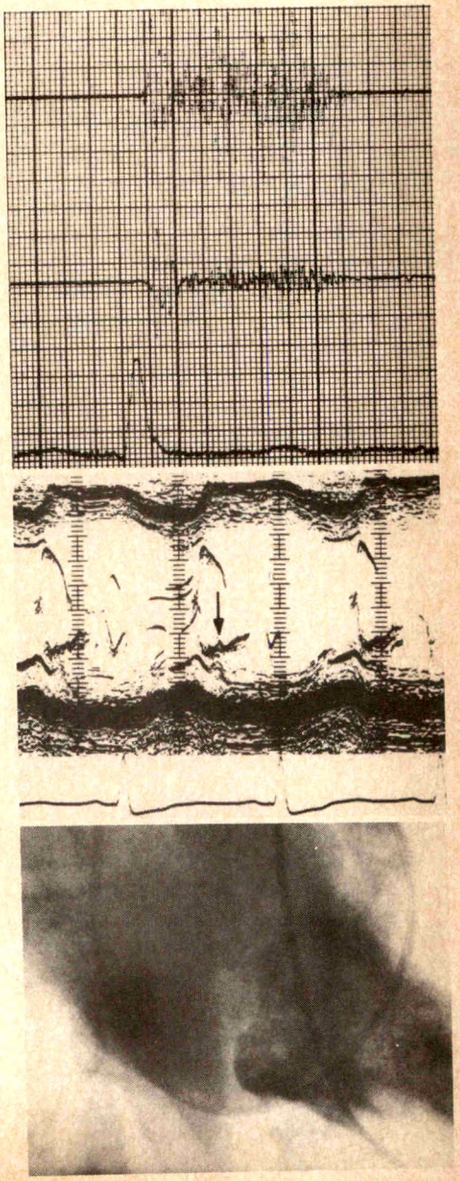

FIGURE 4. Case 6. Phonocardiogram (pansystolic murmur), echocardiogram (coarse diastolic fluttering [**arrow**]), and cine left ventriculogram (mitral valve prolapse and marked mitral regurgitation) repeated in same patient as in Figure 3 eight years later, after chordal rupture (see Figures 1 and 3).

In reviewing our 25 cases, we noted a new echocardiographic sign, i.e., coarse diastolic fluttering of the posterior leaflet as the transducer was angled toward the apex of the left ventricle below the mitral valve.[33] We also noted on cine left ventriculography in the right anterior oblique projection a late diastolic fluttering of the thickened mitral leaflet.[33] These echocardiographic and angiographic findings will be published separately.

Chordal rupture in MVP may be due to increased tension resulting from the enlarged area of the cusp[34] and to degeneration of collagen within the central core of the chordae.[27]

Carpentier et al[26] described the "pellucid" or fibroelastic mitral valve as a separate pathologic entity frequently associated with chordal rupture. Unfortunately, we have not recognized the pathologic changes described by these investigators.

Chordal rupture should be added to the list of complications that may interrupt the general benign course of MVP. Although we have not examined all of our first 100 patients with MVP seen before 1972 and described in 1973,[2] we have follow-up evaluation on most of these patients: Two of our patients with ruptured chordae tendineae belong to this group of patients yielding an incidence of chordal rupture of at least 2% over a 13-year follow-up period. Admittedly, our patients represent a selected group of patients referred to a cardiology service, and the incidence of ruptured chordae may be smaller in an unselected group of patients with MVP. Considering the prevalence of MVP that affects 5 to 6% of the population, the risk of any patient with this syndrome having chordal rupture is small.[3] However, MVP is the most frequent cause of ruptured chordae tendineae and, therfore, the term "idiopathic" should no longer be used to designate most cases of ruptured chordae tendineae.[10]

Acknowledgment: We acknowledge the cooperation of the full-time and practicing cardiologists of Saint Francis Hospital and Medical Center, whose cases have been incorporated in this study. The secretarial assistance of Dorothea Murray is greatly appreciated.

BEHIND THE FACE OF HYPERTENSION

New evidence for central control

For the stress-provoked hypertensive

"Patients with essential hypertension may have exaggerated sympathetic nervous system responses to everyday stresses."[1]

Effective central control of blood pressure

Tablets of 0.1, 0.2, 0.3 mg

Catapres®

(clonidine HCl)

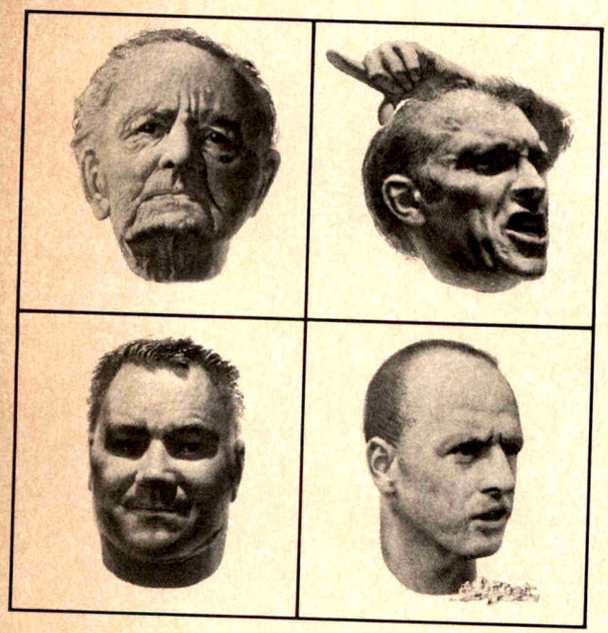
Hypertension

Please see last page for brief summary, including warnings, precautions, and adverse reactions.

BEHIND THE FACE OF HYPERTENSION

New evidence for central control

Catapres®
(clonidine HCl)
Hypertension



Catapres®

(clonidine hydrochloride)
Tablets of 0.1, 0.2, 0.3 mg

Indication: The drug is indicated in the treatment of hypertension. As an antihypertensive drug, Catapres (clonidine hydrochloride) is mild to moderate in potency. It may be employed in a general treatment program with a diuretic and/or other antihypertensive agents as needed for proper patient response.

Warnings: Tolerance may develop in some patients necessitating a reevaluation of therapy.

Usage in Pregnancy: In view of embryotoxic findings in animals, and since information on possible adverse effects in pregnant women is limited to uncontrolled clinical data, the drug is not recommended in women who are or may become pregnant unless the potential benefits outweigh the potential risk to mother and fetus.

Usage in Children: No clinical experience is available with the use of Catapres (clonidine hydrochloride) in children.

Precautions: When discontinuing Catapres (clonidine hydrochloride), reduce the dose gradually over 2 to 4 days to avoid a possible rapid rise in blood pressure and associated subjective symptoms such as nervousness, agitation, and headache. Patients should be instructed not to discontinue therapy without consulting their physician. Rare instances of hypertensive encephalopathy and death have been recorded after cessation of clonidine hydrochloride therapy. A causal relationship has not been established in these cases. It has been demonstrated that an excessive rise in blood pressure, should it occur, can be reversed by resumption of clonidine hydrochloride therapy or by intravenous phentolamine. Patients who engage in potentially hazardous activities, such as operating machinery or driving, should be advised of the sedative effect. This drug may enhance the CNS-depressive effects of alcohol, barbiturates and other sedatives. Like any other agent lowering blood pressure, clonidine hydrochloride should be used with caution in patients with severe coronary insufficiency, recent myocardial infarction, cerebrovascular disease or chronic renal failure.

As an integral part of their overall long-term care, patients treated with Catapres (clonidine hydrochloride) should receive periodic eye examinations. While, except for some dryness of the eyes, no drug-related abnormal ophthalmologic findings have been recorded with Catapres (clonidine hydrochloride), in several studies the drug produced a dose-dependent increase in the incidence and severity of spontaneously occurring retinal degeneration in albino rats treated for 6 months or longer.

Adverse Reactions: The most common reactions are dry mouth, drowsiness and sedation. Constipation, dizziness, headache, and fatigue have been reported. Generally these effects tend to diminish with continued therapy. The following reactions have been associated with the drug, some of them rarely. (In some instances an exact causal relationship has not been established.) These include: Anorexia, malaise, nausea, vomiting, parotid pain, mild transient abnormalities in liver function tests; one report of possible drug-induced hepatitis without icterus and hyperbilirubinemia in a patient receiving clonidine hydrochloride, chlorthalidone and papaverine hydrochloride. Weight gain, transient elevation of blood glucose, or serum creatine phosphokinase; congestive heart failure, Raynaud's phenomenon; vivid dreams or nightmares, insomnia, other behavioral changes, nervousness, restlessness, anxiety and mental depression. Also rash, angioneurotic edema, hives, urticaria, thinning of the hair, pruritus not associated with a rash, impotence, urinary retention, increased sensitivity to alcohol, dryness, itching or burning of the eyes, dryness of the nasal mucosa, pallor, gynecomastia, weakly positive Coombs' test, asymptomatic electrocardiographic abnormalities manifested as Wenckebach period or ventricular trigeminy.

Overdosage: Profound hypotension, weakness, somnolence, diminished or absent reflexes and vomiting followed the accidental ingestion of Catapres (clonidine hydrochloride) by several children from 19 months to 5 years of age. Gastric lavage and administration of an analeptic and vasopressor led to complete recovery within 24 hours. Tolazoline in intravenous doses of 10 mg at 30-minute intervals usually abolishes all effects of Catapres (clonidine hydrochloride) overdosage.

How Supplied: Catapres, brand of clonidine hydrochloride, is available as 0.1 mg (tan) and 0.2 mg (orange) oval, single-scored tablets in bottles of 100 and 1000 and unit dose package of 100. Also available as 0.3 mg (peach) oval, single-scored tablets in bottles of 100.

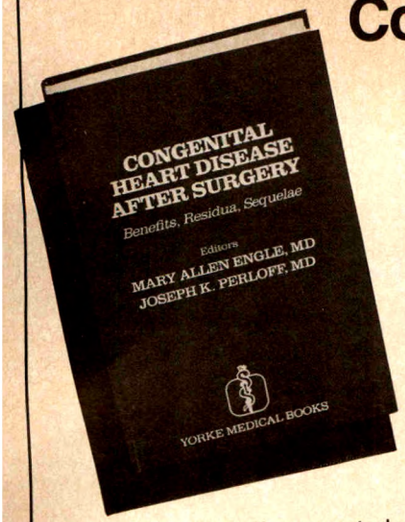
The Latest on the Postoperative Course of Congenital Heart Disease



Congenital Heart Disease After Surgery

Benefits, Residua, Sequelae

edited by **Mary Allen Engle, MD**
Joseph K. Perloff, MD

ISBN 0-914316-37-0, 438 pp., November 1983, $40.00

Thirty-five eminently respected medical researchers and clinicians have produced a book which provides in exhaustive detail much of the current thought, a good deal of which is based on several long-term follow-up studies, on the postoperative course of patients who have undergone surgery for congenital heart disease. It presents a realistic appraisal of problems that some individuals have after surgery for congenital heart disease and at the same time underscores the striking benefits derived from this cardiologic-surgical approach to treatment. This book will help physicians to deal effectively and knowledgeably with the rapidly expanding population of individuals who have had cardiac surgery because of congenital heart disease.

TABLE OF CONTENTS

PROLOGUE—Mary Allen Engle and Joseph K. Perloff
REMARKS—Helen B. Taussig

PART I
SURVEY

1. World survey of the common cardiac malformations: developmental error or genetic variant?
   Helen B. Taussig
2. Ten year and longer follow-up of 1000 consecutive children with cardiac malformations—the University of Minnesota experience
   Ray C. Anderson and James H. Moller

PART II
NONCYANOTIC CONGENITAL HEART DISEASE

3. Long-term follow-up of patients with malformations for which definitive surgical repair has been available for 25 years or more
   Dan G. McNamara and Larry A. Latson
4. Isolated coarctation of the aorta—long-term operative results
   Peter M. Steele, Valentin Fuster, Donald G. Ritter, Dwight C. McGoon
5. Late results after operations for left ventricular outflow tract obstruction
   Michael Jones, Glenn R. Barnhart, Andrew G. Morrow
6. Valvular residua and sequelae after operations for congenital heart disease
   William C. Roberts

PART III
CYANOTIC CONGENITAL HEART DISEASE

7. Late postoperative pulmonary vascular disease—clinical concerns
   William F. Friedman, Miriam F. Heiferman, Joseph K. Perloff
8. Long-term follow-up of patients born cyanotic
   Catherine A. Neill
9. Long-term effects of prosthetic materials
   Dwight C. McGoon
10. Second operations for pulmonary stenosis or insufficiency after repair of tetrology of Fallot
    Paul A. Ebert
11. Modified Mustard operation for simple and complex transposition of the great arteries—five-to-eleven year follow-up
    John E. O'Loughlin, Mary Allen Engle, William A. Gay Jr., Arthur A. Klein, Kathryn H. Ehlers, Aaron R. Levin

PART IV
POSTOPERATIVE FUNCTION

12. Sequelae of atriotomy on the endocardium, conduction system and coronary arteries
    Saroja Bharati and Maurice Lev
13. The myocardium, the conduction system, and general sequelae after surgery for congenital heart disase
    Saroja Bharati and Maurice Lev
14. Electrophysiologic residua and sequelae of surgery for congenital heart defects
    Victoria L. Vetter and Leonard N. Horowitz
15. Development and regression of increased ventricular mass
    Joseph K. Perloff
16. Ventricular performance in adults after operation for congenital heart disease
    Thomas P. Graham, Jr.

PART V
PSYCHOSOCIAL ASPECTS

17. Congenital heart disease and the quality of life
    James A. Manning
18. Pregnancy and its outcome in women with and without surgical treatment of congenital heart disease
    Ruth Whittemore, John C. Hobbins, Mary Allen Engle

PART VI
EPILOGUES

19. The pathologist
    Jesse E. Edwards
20. The pediatric cardiologist
    Alexander S. Nadas
21. The cardiac surgeon
    John W. Kirklin

3M Littmann®

Some great creations are immortal.

At 3M we think our new Littmann® Diagnostic EKG Disposable Electrodes for Resting EKGs are both. Once you try them we think you'll agree.

Why? Because Littmann EKG Electrodes feature the absolute latest in conductive adhesive technology developed in the 3M labs. Now, you can use an electrode that has a progressive, unique solid gel adhesive backing that gives you fast, accurate, reliable tracings. No other electrode...Welsh bulb or disposable...can compare with the new Littmann EKG Electrode.

You'll find your nurse will save time—especially on difficult-to-monitor patients. The unique adhesive lets your nurse simply peel off the electrode...place it on the patient...and start the trace. The solid gel adhesive also permits repositioning, if necessary, for the best possible results.

We think you'll want to stick with our new creation a long time. Once you see a trace, we think you—and your nurse—will agree. We'll even send you a free supply of Littmann EKG Electrodes to get you started.

To get a free Littmann Diagnostic Electrodes Starter Kit for Resting EKGs, have your nurse or office manager clip the coupon and send it in.

Outside of the United States, contact the local 3M subsidiary. In Canada, contact 3M Canada, Inc., P.O. Box 5757, London, Ontario, N6A 4T1, 1-800-268-9696.

Visken® (pindolol)

5-mg and 10-mg Tablets

Before prescribing or administering, see package circular for full product information. The following is a brief summary.

INDICATIONS AND USAGE
Visken® (pindolol) is indicated in the management of hypertension. It may be used alone or concomitantly with other antihypertensive agents, particularly with a thiazide type diuretic.

CONTRAINDICATIONS
Visken (pindolol) is contraindicated in: 1) bronchial asthma; 2) overt cardiac failure; 3) cardiogenic shock; 4) second and third degree heart block; 5) severe bradycardia; (see Warnings).

WARNINGS
Cardiac Failure: Sympathetic stimulation may be a vital component supporting circulatory function in patients with congestive heart failure, and its inhibition by beta-blockade may precipitate more severe failure. Although beta-blockers should be avoided in overt congestive heart failure, if necessary, Visken (pindolol) can be used with caution in patients with a history of failure who are well-compensated, usually with digitalis and diuretics. Beta-adrenergic blocking agents do not abolish the inotropic action of digitalis on heart muscle.

In Patients Without A History of Cardiac Failure: In patients with latent cardiac insufficiency, continued depression of the myocardium with beta-blocking agents over a period of time can in some cases lead to cardiac failure. At the first sign or symptom of impending cardiac failure, patients should be fully digitalized and/or be given a diuretic, and the response observed closely. If cardiac failure continues, despite adequate digitalization and diuretic, Visken (pindolol) therapy should be withdrawn (gradually if possible).

Exacerbation of Ischemic Heart Disease Following Abrupt Withdrawal: Hypersensitivity to catecholamines has been observed in patients withdrawn from beta-blocker therapy; exacerbation of angina and, in some cases, myocardial infarction have occurred after *abrupt* discontinuation of such therapy. When discontinuing chronically administered Visken (pindolol), particularly in patients with ischemic heart disease, the dosage should be gradually reduced over a period of one to two weeks and the patient should be carefully monitored. If angina markedly worsens or acute coronary insufficiency develops, Visken (pindolol) administration should be reinstituted promptly, at least temporarily, and other measures appropriate for the management of unstable angina should be taken. Patients should be warned against interruption or discontinuation of therapy without the physician's advice. Because coronary artery disease is common and may be unrecognized, it may be prudent not to discontinue Visken (pindolol) therapy abruptly even in patients treated only for hypertension.

Nonallergic Bronchospasm (e.g., chronic bronchitis, emphysema)—Patients with Bronchospastic Diseases Should in General Not Receive Beta-Blockers: Visken (pindolol) should be administered with caution since it may block bronchodilation produced by endogenous or exogenous catecholamine stimulation of $beta_2$ receptors.

Major Surgery: Because beta blockade impairs the ability of the heart to respond to reflex stimuli and may increase the risks of general anesthesia and surgical procedures, resulting in protracted hypotension or low cardiac output, it has generally been suggested that such therapy should be withdrawn several days prior to surgery. Recognition of the increased sensitivity to catecholamines of patients recently withdrawn from beta-blocker therapy, however, has made this recommendation controversial. If possible, beta-blockers should be withdrawn well before surgery takes place. In the event of emergency surgery, the anesthesiologist should be informed that the patient is on beta-blocker therapy. The effects of Visken® (pindolol) can be reversed by administration of beta-receptor agonists such as isoproterenol, dopamine, dobutamine, or levarterenol. Difficulty in restarting and maintaining the heart beat has also been reported with beta-adrenergic receptor blocking agents.

Diabetes and Hypoglycemia: Beta-adrenergic blockade may prevent the appearance of premonitory signs and symptoms (e.g., tachycardia and blood pressure changes) of acute hypoglycemia. This is especially important with labile diabetics. Beta-blockade also reduces the release of insulin in response to hyperglycemia; therefore, it may be necessary to adjust the dose of antidiabetic drugs.

Thyrotoxicosis: Beta-adrenergic blockade may mask certain clinical signs (e.g., tachycardia) of hyperthyroidism. Patients suspected of developing thyrotoxicosis should be managed carefully to avoid abrupt withdrawal of beta-blockade which might precipitate a thyroid crisis.

PRECAUTIONS
Impaired Renal or Hepatic Function: Beta-blocking agents should be used with caution in patients with impaired hepatic or renal function. Poor renal function has only minor effects on Visken (pindolol) clearance, but poor hepatic function may cause blood levels of Visken (pindolol) to increase substantially.

Information for Patients: Patients, especially those with evidence of coronary artery insufficiency, should be warned against interruption or discontinuation of Visken (pindolol) therapy without the physician's advice. Although cardiac failure rarely occurs in properly selected patients, patients being treated with beta-adrenergic blocking agents should be advised to consult the physician at the first sign or symptom of impending failure.

Drug Interactions: Catecholamine-depleting drugs (e.g., reserpine) may have an additive effect when given with beta-blocking agents. Patients receiving Visken (pindolol) plus a catecholamine depleting agent should, therefore, be closely observed for evidence of hypotension and/or marked bradycardia which may produce vertigo, syncope, or postural hypotension.

Visken (pindolol) has been used with a variety of antihypertensive agents, including hydrochlorothiazide, hydralazine, and guanethidine without unexpected adverse interactions.

Carcinogenesis, Mutagenesis, Impairment of Fertility: In chronic oral toxicologic studies (one to two years) in mice, rats, and dogs, Visken (pindolol) did not produce any significant toxic effects. In two-year oral carcinogenicity studies in rats and mice in doses as high as 59 mg/kg/day and 124 mg/kg/day (50 and 100 times the maximum recommended human dose), respectively, Visken (pindolol) did not produce any neoplastic, preneoplastic, or nonneoplastic pathologic lesions. In fertility and general reproductive performance studies in rats, Visken (pindolol) caused no adverse effects at a dose of 10 mg/kg.

In the male fertility and general reproductive performance test in rats, definite toxicity characterized by mortality and decreased weight gain was observed in the group given 100 mg/ kg/day. At 30 mg/kg/day, decreased mating was associated with testicular atrophy and/or decreased spermatogenesis. This response is not clearly drug related, however, as there was no dose response relationship within this experiment and no similar effect on testes of rats administered Visken (pindolol) as a dietary admixture for 104 weeks. There appeared to be an increase in prenatal mortality in males given 100 mg/kg but development of offspring was not impaired.

In females administered Visken (pindolol) prior to mating through day 21 of lactation, mating behavior was decreased at 100 mg/kg and 30 mg/kg. At these dosages there also was increased mortality of offspring. Prenatal mortality was increased at 10 mg/kg but there was not a clear dose response relationship in this experiment. There was an increased resorption rate at 100 mg/kg observed in females necropsied on the 15th day of gestation.

Pregnancy—Category B: Studies in rats and rabbits exceeding 100 times the maximum recommended human doses, revealed no embryotoxicity or teratogenicity. Since there are no adequate and well-controlled studies in pregnant women, and since animal reproduction studies are not always predictive of human response, Visken (pindolol), as with any drug, should be employed during pregnancy only if the potential benefit justifies the potential risk to the fetus.

Nursing Mothers: Since Visken (pindolol) is secreted in human milk, nursing should not be undertaken by mothers receiving the drug.

Pediatric Use: Safety and effectiveness in children have not been established.

CLINICAL LABORATORY
Minor persistent elevations in serum transaminases (SGOT, SGPT) have been noted in 7% of patients during Visken (pindolol) administration, but progressive elevations were not observed and liver injury has not been reported in the medical literature over a ten (10) year period of marketing. Alkaline phosphatase, lactic acid dehydrogenase (LDH) and uric acid are also elevated on rare occasions. The significance of these findings is unknown.

ADVERSE REACTIONS
Most adverse reactions have been mild. The incidences listed in the following table are derived from 12 week comparative double-blind, parallel design trials in hypertensive patients given Visken (pindolol) as monotherapy, given various active control drugs as monotherapy, or given placebo. Data for Visken (pindolol) and the positive controls were pooled from several trials because no striking differences were seen in the individual studies, with one exception. The frequency of edema was noticeably higher in positive control trials (16% Visken (pindolol) vs 9% positive control) than in placebo controlled trials (6% Visken (pindolol) vs 3% placebo). The table includes adverse reactions reported in greater than 2% of Visken (pindolol) patients and other selected important reactions.

Body System/ Adverse Reaction	Total (Volunteered and Elicited) Visken (pindolol) (N = 322) %	Active controls* (N = 188) %	Placebo (N = 78) %
Central Nervous System			
Anxiety	4	< 1	1

Pruritus	2	< 1	0
Rash	2	3	3

* Active Controls: Patients received either propranolol, α-methyldopa or a diuretic (hydrochlorothiazide or chlorthalidone).

More than 7 million patient-years of experience

The following selected (potentially important) adverse reactions were seen in 2% or fewer patients and their relationship to Visken (pindolol) is uncertain. AUTONOMIC NERVOUS SYSTEM: hyperhidrosis; CARDIOVASCULAR: bradycardia, claudication, cold extremities, heart block, hypotension, syncope, tachycardia; GASTROINTESTINAL: diarrhea, vomiting; RESPIRATORY: wheezing; UROGENITAL: impotence, pollakiuria; MISCELLANEOUS: eye discomfort or burning eyes.

POTENTIAL ADVERSE EFFECTS
In addition, other adverse effects not listed above have been reported with other beta-adrenergic blocking agents and should be considered potential adverse effects of Visken (pindolol).

Central Nervous System: Reversible mental depression progressing to catatonia; an acute reversible syndrome characterized by disorientation for time and place, short-term memory loss, emotional lability, slightly clouded sensorium, and decreased performance on neuropsychometrics.

Cardiovascular: Intensification of AV block. See CONTRAINDICATIONS.

Allergic: Erythematous rash; fever combined with aching and sore throat; laryngospasm; respiratory distress.

Hematologic: Agranulocytosis; thrombocytopenic and non-thrombocytopenic purpura.

Gastrointenstinal: Mesenteric arterial thrombosis; ischemic colitis.

Miscellaneous: Reversible alopecia; Peyronie's disease.

The oculomucocutaneous syndrome associated with the beta-blocker practolol has not been reported with Visken (pindolol) during investigational use and extensive foreign experience amounting to over 4 million patient-years.

OVERDOSAGE
No specific information on emergency treatment of overdosage is available. Therefore, on the basis of the pharmacologic actions of Visken (pindolol), the following general measures should be employed as appropriate in addition to gastric lavage:

Excessive Bradycardia: administer atropine; if there is no response to vagal blockade, administer isoproterenol cautiously.

Cardiac Failure: digitalize the patient and/or administer diuretic. It has been reported that glucagon may be useful in this situation.

Hypotension: administer vasopressors, e.g., epinephrine or levarterenol, with serial monitoring of blood pressure. (There is evidence that epinephrine may be the drug of choice.)

Bronchospasm: administer a $beta_2$ stimulating agent such as isoproterenol and/or a theophylline derivative.

A case of an acute overdosage has been reported with an intake of 500 mg of Visken (pindolol) by a hypertensive patient. Blood pressure increased and heart rate was ≥ 80 beat/min. Recovery was uneventful. In another case 250 mg of Visken (pindolol) was taken with 150 mg diazepam and 50 mg nitrazepam, producing coma and hypotension. The patient recovered in 24 hours.

DOSAGE AND ADMINISTRATION
The dosage of Visken (pindolol) should be individualized. The recommended initial dose of Visken (pindolol) is 5 mg b.i.d. alone or in combination with other antihypertensive agents. An antihypertensive response usually occurs within the first week of treatment. Maximal response, however, may take as long as or occasionally longer than two weeks. If a satisfactory reduction in blood pressure does not occur within 3-4 weeks, the dose may be adjusted in increments of 10 mg per day at these intervals up to a maximum of 60 mg per day.

HOW SUPPLIED
White, round, scored tablets: 5 mg and 10 mg, packages of 100. 5 mg tablets embossed "VISKEN 5" on one side, and "78-111" and scored on other side (NDC 0078-0111-05). 10 mg tablets embossed "VISKEN 10" on one side, and "78-73" and scored on other side (NDC 0078-0073-05).

INFECTIOUS COMPLICATIONS OF NEOPLASTIC DISEASE

Controversies in Management

Edited by Arthur E. Brown, MD, and Donald Armstrong, MD
0-914316-43-5, approx. 400 pp., Oct. 1984, $40.00 casebound

About the book

Derived from a symposium sponsored by the Infectious Disease Service, Department of Medicine and the Department of Pediatrics, Memorial Sloan-Kettering Cancer Center, New York City, and Cornell University Medical College, New York City, this book presents the latest thinking by international authorities, all of whom were invited to present findings in their area of expertise on the diagnosis, treatment, and prevention of various bacterial, fungal, viral, and parasitic infections presenting in patients with neoplastic disease.

This is not just another "proceedings" volume. Rather it is an edited work, with papers by investigators who submitted definitive preparations for publication. Furthermore, the authors take a strong position on their topics, ask probing questions and promote a stimulating forum of controversy.

The result is a concise, dynamic study that belongs in the professional library of every physician treating patients with neoplastic disease.

About the Editors

Arthur E. Brown, MD, is Assistant Attending Physician, Memorial Sloan-Kettering Cancer Center, and Assistant Professor of Medicine and Pediatrics, Cornell University Medical College.

Donald Armstrong, MD, is Attending Physician; Chief of Service; Director, Microbiology Laboratory, Memorial Sloan-Kettering Cancer Center, and Professor of Medicine, Cornell University Medical College

Table of Contents

PART I. DIAGNOSIS AND TREATMENT

Introduction and epidemiology
Neutropenia, fever, and infection
Significance of serum bactericidal activity in gram-negative bacillary bacteremia in patients with and without granulocytopenia
Approaching the controversies in antibacterial management of cancer patients
Can antibacterial therapy be discontinued in persistently febrile granulocytopenic cancer patients?
Quantitative blood cultures: a review of 52 years
Viral infections in patients with neoplastic disease: diagnosis and therapy
Parasitic diseases in immunocompromised hosts

PART II. AIDS

Cluster of cases of the acquired immune deficiency syndrome: patients linked by sexual contact
Model-based approach to an analysis of a cluster pattern
Association between acquired immune deficiency syndrome and sexual contact: an analysis of the incidence pattern
Acquired immune deficiency syndrome (AIDS) trends in the United States
Assessment of therapy for Pneumocystis carinii pneumonia - PCP Therapy Project Group

PART III. PREVENTION

Granulocyte transfusions
Leukocyte transfusions: thinking twice
Chemoprophylaxis of bacterial infections in granulocytopenic patients
Chemoprophylaxis of fungal infections
Legionnaires' Disease: aspects of nosocomial infection
Immunoprophylaxis and serotherapy of bacterial infections
Immunoprophylaxis of varicella-zoster infections
Current status of prophylaxis of infection with protected environments
Protected environments are discomforting and expensive and do not offer meaningful protection

Clinical Clues to MIXED ANGINA *No. 1*

Thirty seconds ago he was reading

He wasn't exercising; his myocardial oxygen demand didn't increase. Yet now he's having an angina attack.

That's the unpredictability of MIXED ANGINA—vasoconstriction coexisting with fixed coronary lesion, to produce a critical reduction of myocardial blood flow.

And because vasoconstriction is an unpredictable event, ischemia and pain occur unpredictably:

- at rest, or even during sleep
- at varying levels of exercise
- upon exposure to cold
- under emotional stress
- diurnally, typically in the morning

PROCARDIA® (nifedipine) is a primary therapy for the patient with MIXED ANGINA. It prevents vasoconstriction in both large coronary arteries and coronary arterioles to maintain myocardial blood flow and oxygen supply. At the same time, PROCARDIA dilates peripheral arteries to reduce afterload and myocardial oxygen demand.

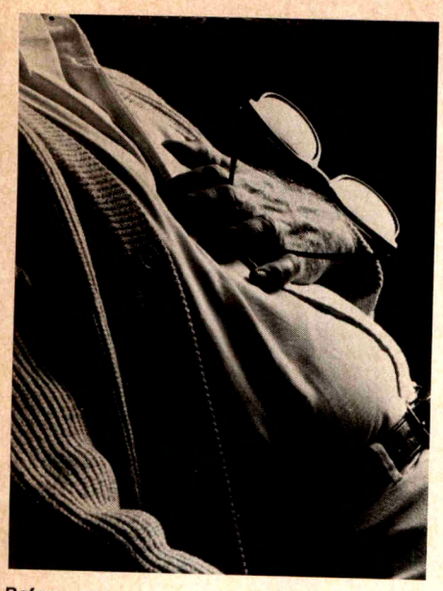
As a result, PROCARDIA can significantly reduce your patient's angina attack rate and need for nitroglycerin!

PROCARDIA®
(NIFEDIPINE) *Capsules 10 mg*

Primary Protection in
MIXED ANGINA

Please see PROCARDIA® (nifedipine) brief summary on next page.

Thirty seconds ago he was reading.



PROCARDIA®
(NIFEDIPINE) *Capsules 10 mg*

PRIMARY PROTECTION IN MIXED ANGINA

Usual Effective Dosage: 30 to 60 mg/day

For most patients, titrate over 7 to 14 days, using the patient's blood pressure response, attack frequency, sublingual nitroglycerin intake and activity level as a guide. Titration may be more rapid (e.g., 3 days) if symptoms warrant and the patient is observed closely.

Because PROCARDIA decreases peripheral vascular resistance (occasional patients have had excessive hypotension), careful monitoring of blood pressure during initial administration and upward dosage titration is suggested, especially for patients taking drugs known to lower blood pressure. Occasional patients have developed increased frequency, duration or severity of angina on starting PROCARDIA or at the time of dosage increases.

A Favorable Safety Profile

Most frequently reported side effects, usually mild, are dizziness or lightheadedness, peripheral edema, nausea, weakness, headache and flushing, each occurring in about 10% of patients, transient hypotension in about 5%, palpitation in about 2% and syncope in about 0.5%.

Reference:

1. Stone PH, Muller JE, Turi ZG, et al: Efficacy of nifedipine therapy in patients with refractory angina pectoris: Significance of the presence of coronary vasospasm. *Am Heart J* 106:644-652, 1983.

Brief Summary
PROCARDIA® (nifedipine) Capsules
For Oral Use

INDICATIONS AND USAGE: I. Vasospastic Angina: PROCARDIA (nifedipine) is indicated for the management of vasospastic angina confirmed by any of the following criteria: 1) classical pattern of angina at rest accompanied by ST segment elevation, 2) angina or coronary artery spasm provoked by ergonovine, or 3) angiographically demonstrated coronary artery spasm. In those patients who have had angiography, the presence of significant fixed obstructive disease is not incompatible with the diagnosis of vasospastic angina, provided that the above criteria are satisfied. PROCARDIA may also be used where the clinical presentation suggests a possible vasospastic component but where vasospasm has not been confirmed, e.g., where pain has a variable threshold on exertion or in unstable angina where electrocardiographic findings are compatible with intermittent vasospasm, or when angina is refractory to nitrates and/or adequate doses of beta blockers.

II. Chronic Stable Angina (Classical Effort-Associated Angina): PROCARDIA is indicated for the management of chronic stable angina (effort-associated angina) without evidence of vasospasm in patients who remain symptomatic despite adequate doses of beta blockers and/or organic nitrates or who cannot tolerate those agents.

In chronic stable angina (effort-associated angina) PROCARDIA has been effective in controlled trials of up to eight weeks duration in reducing angina frequency and increasing exercise tolerance, but confirmation of sustained effectiveness and evaluation of long-term safety in these patients are incomplete.

Controlled studies in small numbers of patients suggest concomitant use of PROCARDIA and beta-blocking agents may be beneficial in patients with chronic stable angina, but available information is not sufficient to predict with confidence the effects of concurrent treatment, especially in patients with compromised left ventricular function or cardiac conduction abnormalities. When introducing such concomitant therapy, care must be taken to monitor blood pressure closely since severe hypotension can occur from the combined effects of the drugs. (See WARNINGS.)

CONTRAINDICATIONS: Known hypersensitivity reaction to PROCARDIA.

WARNINGS: Excessive Hypotension: Although in most patients, the hypotensive effect of PROCARDIA is modest and well tolerated, occasional patients have had excessive and poorly tolerated hypotension. These responses have usually occurred during initial titration or at the time of subsequent upward dosage adjustment, and may be more likely in patients on concomitant beta blockers.

Severe hypotension and/or increased fluid volume requirements have been reported in patients receiving PROCARDIA together with a beta blocking agent who underwent coronary artery bypass surgery using high dose fentanyl anesthesia. The interaction with high dose fentanyl appears to be due to the combination of PROCARDIA and a beta blocker, but the possibility that it may occur with PROCARDIA alone, with low doses of fentanyl, in other surgical procedures, or with other narcotic analgesics cannot be ruled out. In PROCARDIA treated patients where surgery using high dose fentanyl anesthesia is contemplated, the physician should be aware of these potential problems and, if the patient's condition permits, sufficient time (at least 36 hours) should be allowed for PROCARDIA to be washed out of the body prior to surgery.

Increased Angina: Occasional patients have developed well-documented increased frequency, duration or severity of angina on starting PROCARDIA or at the time of dosage increases. The mechanism of this response is not established but could result from decreased coronary perfusion associated with decreased diastolic pressure with increased heart rate, or from increased demand resulting from increased heart rate alone.

Beta Blocker Withdrawal: Patients recently withdrawn from beta blockers may develop a withdrawal syndrome with increased angina, probably related to increased sensitivity to catecholamines. Initiation of PROCARDIA treatment will not prevent this occurrence and might be expected to exacerbate it by provoking reflex catecholamine release. There have been occasional reports of increased angina in a setting of beta blocker withdrawal and PROCARDIA initiation. It is important to taper beta blockers if possible, rather than stopping them abruptly before beginning PROCARDIA.

Congestive Heart Failure: Rarely, patients, usually receiving a beta blocker, have developed heart failure after beginning PROCARDIA. Patients with tight aortic stenosis may be at greater risk for such an event.

PRECAUTIONS: General: Hypotension: Because PROCARDIA decreases peripheral vascular resistance, careful monitoring of blood pressure during the initial administration and titration of PROCARDIA is suggested. Close observation is especially recommended for patients already taking medications that are known to lower blood pressure. (See WARNINGS.)

Peripheral edema: Mild to moderate peripheral edema, typically associated with arterial vasodilation and not due to left ventricular dysfunction, occurs in about one in ten patients treated with PROCARDIA (nifedipine). This edema occurs primarily in the lower extremities and usually responds to diuretic therapy. With patients whose angina is complicated by congestive heart failure, care should be taken to differentiate this peripheral edema from the effects of increasing left ventricular dysfunction.

Laboratory tests: Rare, usually transient, but occasionally significant elevations of enzymes such as alkaline phosphatase, CPK, LDH, SGOT and SGPT have been noted. The relationship to PROCARDIA therapy is uncertain in most cases, but probable in some. These laboratory abnormalities have rarely been associated with clinical symptoms, however, cholestasis with or without jaundice has been reported. Rare instances of allergic hepatitis have been reported.

Limited clinical studies have demonstrated a moderate but statistically significant decrease in platelet aggregation and increase in bleeding time in some PROCARDIA patients. No clinical significance for these findings has been demonstrated.

Drug interactions: Beta-adrenergic blocking agents: (See Indications and Warnings.) Experience in over 1400 patients in a non-comparative clinical trial has shown that concomitant administration of PROCARDIA and beta-blocking agents is usually well tolerated, but there have been occasional literature reports suggesting that the combination may increase the likelihood of congestive heart failure, severe hypotension or exacerbation of angina.

Long-acting nitrates: PROCARDIA may be safely co-administered with nitrates, but there have been no controlled studies to evaluate the antianginal effectiveness of this combination.

Digitalis: Administration of PROCARDIA with digoxin increased digoxin levels in nine of twelve normal volunteers. The average increase was 45%. Another investigator found no increase in digoxin levels in thirteen patients with coronary artery disease. In an uncontrolled study of over two hundred patients with congestive heart failure during which digoxin blood levels were not measured, digitalis toxicity was not observed. Since there have been isolated reports of patients with elevated digoxin levels, it is recommended that digoxin levels be monitored when initiating, adjusting, and discontinuing PROCARDIA to avoid possible over- or under-digitalization.

Coumarin anticoagulants: There have been rare reports of increased prothrombin time in patients taking coumarin anticoagulants to whom PROCARDIA was administered. However, the relationship to PROCARDIA therapy is uncertain.

When given to rats prior to mating, nifedipine caused reduced fertility at a dose approximately 30 times the maximum recommended human dose.

Carcinogenesis, mutagenesis, impairment of fertility: Nifedipine was administered orally to rats for two years and was not shown to be carcinogenic. When given to rats prior to mating, nifedipine caused reduced fertility at a dose approximately 30 times the maximum recommended human dose. *In vivo* mutagenicity studies were negative.

Pregnancy: Pregnancy Category C. Please see full prescribing information with reference to teratogenicity in rats, embryotoxicity in rats, mice and rabbits, and placental abnormalities in monkeys.

ADVERSE REACTIONS: The most common adverse events include dizziness or lightheadedness, peripheral edema, nausea, weakness, headache and flushing, each occurring in about 10% of patients, transient hypotension in about 5%, palpitation in about 2% and syncope in about 0.5%. Syncopal episodes did not recur with reduction in the dose of PROCARDIA or concomitant antianginal medication. Additionally, the following have been reported: muscle cramps, nervousness, dyspnea, nasal and chest congestion, diarrhea, constipation, inflammation, joint stiffness, shakiness, sleep disturbances, blurred vision, difficulties in balance, dermatitis, pruritus, urticaria, fever, sweating, chills, sexual difficulties, thrombocytopenia, allergic hepatitis, and gingival hyperplasia. Very rarely, introduction of PROCARDIA therapy was associated with an increase in anginal pain, possibly due to associated hypotension.

In addition, more serious adverse events were observed, not readily distinguishable from the natural history of the disease in these patients. It remains possible, however, that some or many of these events were drug related. Myocardial infarction occurred in about 4% of patients and congestive heart failure or pulmonary edema in about 2%. Ventricular arrhythmias or conduction disturbances each occurred in fewer than 0.5% of patients.

HOW SUPPLIED: Each orange, soft gelatin PROCARDIA CAPSULE contains 10 mg of nifedipine. PROCARDIA CAPSULES are supplied in bottles of 100 (NDC 0069-2600-66), 300 (NDC 0069-2600-72), and unit dose (10x10) (NDC 0069-2600-41). The capsules should be protected from light and moisture and stored at controlled room temperature 59° to 77°F (15° to 25°C) in the manufacturer's original container.

Findings on Endomyocardial Biopsy in Infants and Children with Dilated Cardiomyopathy

ALAN B. LEWIS, MD, HARRY B. NEUSTEIN, MD, MASATO TAKAHASHI, MD, and PAUL R. LURIE, MD

Fifteen infants and children with dilated cardiomyopathy underwent transvascular endomyocardial biopsy. The light and electron microscopic findings were reviewed to evaluate the presence of lymphocytes as an indicator of active myocarditis. Both ventricles were biopsied in 13 patients, and the right ventricle only was biopsied in 2. None of the endomyocardial specimens obtained by biopsy revealed an inflammatory process. Interstitial fibrosis, myofiber hypertrophy, degeneration and necrosis were found. Ultrastructural abnormalities of the mitochrondria, T tubules or Z bands were noted in approximately one-third of patients. Persistent, active myocarditis is an uncommon cause of dilated cardiomyopathy in children. Immunosuppressive therapy, which may be harmful, should be considered only after myocardial inflammation has been documented by endomyocardial biopsy.

(Am J Cardiol 1985;55:143–145)

Dilated cardiomyopathy (DC) remains a therapeutic challenge because it lacks specific etiologic factors. Goodwin[1] suggested that an antecedent viral infection may trigger a chronic inflammatory reaction of the myocardium in some patients. Recent studies in adults with idiopathic DC have reported inflammation in 5 to 63% of patients studied by transvascular endomyocardial biopsy techniques.[2–5] Clinical and hemodynamic improvement was noted in 10 of the 17 reported patients treated with immunosuppressive agents after biopsy confirmation of myocardial inflammation.[2,3] However, these observations were made in noncontrolled clinical trials in adults. The present report presents our experience in 15 infants and children with DC who underwent endomyocardial biopsy.

Methods

Patients: Since 1975, 32 patients with cardiomyopathies have undergone transvascular endomyocardial biopsy at the Childrens Hospital of Los Angeles. Fifteen infants and children had DC and constitute the study group of this report. The other 17 patients had hypertrophic or restrictive cardiomyopathy and were excluded from further analysis. The 15 study patients had chronic congestive heart failure that could not be attributed to a structural cardiac malformation. Echocardiography was performed before biopsy in all patients, using standard techniques.

Endomyocardial biopsy: All patients underwent routine diagnostic left- and right-sided cardiac catheterization and biplane cineangiography before endomyocardial biopsy. Emphasis was placed on the angiographic demonstration of normal coronary arteries. Transvascular endomyocardial biopsy was then performed as previously described.[6,7] Right and left ventricular (RV and LV) biopsies were attempted in all patients. Each biopsy sample obtained was approximately 1.5 × 1 × 1 mm or less and was placed into 2% buffered glutaraldehyde for light microscopy and transmission electron microscopy. Both light and electron microscopic sections were examined for evidence of inflammation.

Results

The clinical and echocardiographic features of the 15 patients with DC are summarized in Table I. The mean age (± standard error of the mean) at the time of biopsy was 4.6 ± 1.4 years (range 1 month to 15 years). The mean duration of illness was 0.9 ± 0.3 years (range 1 month to 5 years). In 9 patients, cardiac biopsy was performed within 6 months and in 4 patients within 2 months of the onset of congestive heart failure.

The LV end-diastolic dimensions in DC patients were uniformly increased and averaged 166% of the mean for normal subjects.[8] The LV shortening fraction was depressed in all patients (mean 13 ± 2%) and the ratio of

13	4 mo	M	1 mo	4.0	9	0.24	+ (1.5 yr)
14	15.3 yr	M	1 yr	7.3	23	...	+ (15.4 yr)
15	7 mo	M	7 mo	4.2	10	0.44	0

Dd = end-diastolic dimension; LV = left ventricular; PEP/ET = ratio of preejection period to ejection time; SF = shortening fraction; + = yes; 0 = no.

LV preejection period to ejection time was prolonged in 14 patients (mean 0.58 ± 0.05).

Antibody titers against echo, Coxsackie, EBV and adenoviruses had been obtained at the time of initial presentation in 11 patients and were considered negative (titer ≤1:8) in all but 1 child, who once had a titer against Coxsackie B_2 of 1:32. Serum carnitine levels were measured in 2 patients and were normal in both. Two patients had a family history of cardiomyopathy. In 1 family all affected persons were male (patient 13).[9]

RV and LV biopsies were performed successfully in 13 patients; in 2 patients, only RV specimens could be obtained. A total of 76 endomyocardial biopsy specimens were obtained. No evidence of an inflammatory cell process was found in any patient. Interstitial fibrosis (7 patients), myofiber degeneration (7 patients) or hypertrophy (6 patients) were the most frequently observed abnormalities. Ultrastructural changes in the mitochondria (3 patients), T tubules (4 patients) and Z-band configuration (3 patients) were noted less frequently.

Discussion

Recent reports have described lymphocytic myocardial infiltration in 5 to 63% of adult patients with previously unexplained DC.[2–5] These observations have provided impetus for the use of antiinflammatory agents such as prednisone and azathioprine for therapy. Indeed, these early reports suggest at least short-term improvement or stabilization in some patients with biopsy-proved inflammatory cardiomyopathy after treatment. However, none of these studies were controlled and the use of such therapy remains controversial.

Several investigators have proposed a viral etiology for persistent myocarditis.[1,10–12] However, documentation of an antecedent viral infection is uncommon in most patients with unexplained DC.[2] In persons with active viral myocarditis, antiinflammatory agents may be hazardous; animal studies suggest that immunosuppression may exacerbate viral myocarditis by inhibiting interferon synthesis.[13,14]

Zee-Cheng et al[3] postulated that the presence of T lymphocytes in the myocardium supports the concept that myocardial damage may be mediated by the immune system. Nevertheless, whether the inflammatory cell response is actually destructive, reparative or merely reactive to a more primary myocardial degenerative process is not known.[15] Two recent studies showed that the symptomatic improvement in some patients treated with corticosteroids did not correlate with the presence or absence of inflammatory cells in the myocardium.[16,17]

The chronic use of immunosuppressive agents such as prednisone and azathioprine in children carries a considerable risk of adverse effects, including potentially life-threatening infection, growth retardation and bone marrow suppression. Therefore, the potential for improving cardiac function must be balanced carefully against the risks of immunosuppressive therapy.

The 15 children in this report represent a fairly typical group of young patients with unexplained DC. Despite the small size of this series, at least several patients might have been expected to show evidence of myocardial inflammation if the incidence of persistent active myocarditis were similar in adults and children.[2–5] We do not believe that inadequacy of biopsy material can explain the lack of inflammatory findings since an average of 5 specimens was obtained in each patient. This compares favorably with the recommendation by Edwards et al[15] of at least 4 samples per patient because of the possibility of focal inflammation. In fact, our technique may maximize the yield, because both ventricles were biopsied in 13 of our patients, whereas only the right ventricle was biopsied in the previously reported adult series.[2–5,15]

Alternatively, a longer duration between the onset of symptoms and performance of endomyocardial biopsy may decrease the incidence of inflammation observed in biopsy specimens. The mean duration of illness in our pediatric patients was 11 months (range 1 month to 5

years) and compares favorably with the mean symptom duration of 17 months (range 1 week to 6 years) in the adult patients reported by Zee-Cheng et al,[3] in whom 63% had at least low-grade inflammatory changes. Patients with the most extensive inflammatory changes usually had been symptomatic for shorter periods before biopsy (less than 4 months).[3] In contrast, 6 children in our series underwent endomyocardial biopsy within 4 months of becoming symptomatic, and no inflammation was observed.

O'Connell et al[18] suggested that myocardial scintigraphy with gallium-67 citrate is a useful noninvasive method of identifying patients with DC who may have inflammatory changes. However, the incidence of biopsy-proved myocarditis was only 36% in patients with a positive gallium-67 scan.[19] One of our patients underwent gallium-67 scanning and was found to have moderate myocardial uptake. However, no evidence of inflammation was noted on any of the 6 biopsy samples obtained within 1 month of scintigraphy. Gallium-67 localizes not only in areas of inflammation and abscess, but also in ischemic regions of the myocardium[20] and muscle undergoing physiologic hypertrophy.[18] Thus, the lack of specificity of gallium-67 scintigraphy limits its usefulness in the definitive diagnosis of myocardial inflammation. Nevertheless, it may be a useful screening agent to aid in the selection of patients for endomyocardial biopsy.[19]

A family history of cardiomyopathy was present in 2 of our patients, 1 of whom had an x-linked mode of inheritance[9]; therefore, hereditary basis for DC may be more common in children than in adults. Nevertheless, the apparently low incidence of myocardial inflammation in this small series of children with DC should not preclude the continued search in other young patients for this condition. However, because the use of immunosuppressive agents carries considerable risk, conclusive documentation of myocardial inflammation by endomyocardial biopsy should be a prerequisite to the initiation of antiinflammatory therapy.

Arrhythmias in Ischemic and Nonischemic Dilated Cardiomyopathy: Prediction of Mortality by Ambulatory Electrocardiography

JOHN HOLMES, MD, SPENCER H. KUBO, MD, ROBERT J. CODY, MD, and PAUL KLIGFIELD, MD

To test the hypothesis that ventricular arrhythmias detected by ambulatory electrocardiography can stratify mortality risk in patients with ischemic and those with nonischemic dilated cardiomyopathy, clinical, hemodynamic and neurohumoral findings were evaluated in 31 patients. By Kaplan-Meier analysis, the total population had 51% survival at 12 months and 19% survival at 25 months. Subgroups based on peak complexity of ventricular arrhythmias included 9 patients with simple ventricular arrhythmias (peak Lown grades 1 to 3) and 22 patients with complex ventricular arrhythmias (peak Lown grades 4 or 5). Clinical variables and baseline catecholamine levels and renin-angiotensin system activity were similar in the simple and complex arrhythmia subgroups. Patients with simple and those with complex arrhythmias were comparable by all hemodynamic indexes except for a higher mean pulmonary capillary wedge pressure in the complex arrhythmia subgroup. Survival was strikingly related to arrhythmias: mortality was 11% (1 of 9) in the simple ventricular arrhythmia subgroup and 59% (13 of 22) in the complex ventricular arrhythmia subgroup ($p < 0.025$ by log-rank test). Twelve patients died suddenly and 2 patients died in circulatory failure, and the risk of death was not affected by the etiology of cardiomyopathy. The higher mortality among the patients with complex arrhythmia could not be explained by the presence of elevated filling pressures alone. Thus, ambulatory electrocardiography can stratify mortality risk among patients with severe ischemic and nonischemic dilated cardiomyopathy. These data are consistent with the hypothesis that complex ventricular arrhythmias represent an independent mortality risk factor in this population.

(Am J Cardiol 1985;55:146–151)

Detection of arrhythmias by ambulatory electrocardiography is of value for the stratification of risk of sudden death in patients who survive myocardial infarction,[1,2] but the independent predictive value of arrhythmias in most other cardiac diseases remains unknown. Although survival in severe congestive heart failure due to dilated cardiomyopathy (DC) has been related to the etiology of DC[3] and to ventricular performance,[3–6] the prognostic value of coexistent arrhythmias on the natural history of this entity remains controversial.[7,8] This study was designed to test the hypothesis that arrhythmias detected by ambulatory electrocardiography can stratify mortality risk in severe DC and to examine whether etiology, hemodynamic profile and neurohumoral status influence the relation of arrhythmias to subsequent mortality.

Methods

Thirty-one patients with severe congestive heart failure due to ischemic or nonischemic DC were enrolled in this study from 1981 to 1983. All patients had been referred for vasodilator therapy because of poor clinical response to digitalis and diuretic drugs. Twenty-five were men and 6 were women, aged 34 to 78 years (mean 56). The mean follow-up period was 14 months (range 2 to 25).

Patients presented with severe congestive heart failure and were separated into ischemic and nonischemic etiologic subgroups (Tables I and II). The diagnosis of ischemic DC was made when there was documented previous myocardial infarction or by demonstration of occlusive coronary disease at cardiac catheterization (Table I). Nonischemic DC was diagnosed in patients with no history of ischemia of presumed idiopathic, postinfectious, postpartum, valvular, or alcoholic origin (Table II). Eleven patients underwent catheterization

with coronary angiography, which confirmed the clinical diagnosis before entry.

Right-sided cardiac catheterization was performed in all patients a mean of 17 days (range 1 to 120) before or after ambulatory electrocardiography. Tests were performed within 10 days of each other in 87% (27 of 31) of the patients. Baseline hemodynamic values were measured while patients were receiving only digoxin and diuretic drugs. Plasma norepinephrine levels and plasma renin activity were measured in 25 and 30 patients respectively. These were obtained at the time of catheterization, according to previously described methods.[9]

At the time of ambulatory electrocardiography, 94% of the patients (29 of 31) were receiving digitalis preparations, 39% (12 of 31) were receiving long-acting nitrates and 26% (8 of 31) were receiving afterload-reducing agents. Antiarrhythmic drugs were continued in 26% (8 of 31) of the study patients during the period of ambulatory electrocardiography and throughout the follow-up period. Serum potassium levels measured at the time of ambulatory electrocardiography were normal in all patients. Serum digoxin levels, available in 23 of 31 patients, were within normal limits in all patients but one, who had only simple arrhythmias. Digitalis and diuretic therapy was continued in 94% of the study patients (29 of 31) after initial evaluation, and all patients subsequently received vasodilator therapy (hydralazine, prazosin, captopril, enalapril or nifedipine). Antiarrhythmic drugs (procainamide and quinidine) were continued during the follow-up period according to the patients' prestudy regimen.

Twenty-four-hour ambulatory electrocardiograms utilized simultaneous precordial recordings of modified leads V_1 and V_5. All recordings were initially scanned by a special technician using computer-assisted analysis (Avionics Trendsetter).

TABLE III Hemodynamic and Neurohumoral Profiles of Patients Based on Ventricular Arrhythmia Profiles

	Simple VPCs	Complex VPCs	p Value
Age (yr)	58 ± 9	55 ± 13	NS

NS = not significant; NYHA = New York Heart Association; VPCs = ventricular premature complexes; W = Wilcoxon rank-sum test.

Arrhythmias were independently evaluated by 2 physicians. Supraventricular arrhythmia analysis included quantification of mean and peak atrial premature complexes (APCs) per 1,000 total beats, and tabulation of APC complex couplets, paroxysmal atrial tachycardia, atrial fibrillation, flutter and sustained atrial tachycardia. Ventricular arrhythmia analysis included quantification of mean and peak ventricular premature complexes (VPCs) per 1,000 total beats, and tabulation of ventricular arrhythmia complexity by the Lown classification system,[10] including grades 3 (multiform, single VPCs), 4A (VPC couplets), 4B (VPC salvos or ventricular tachycardia) and 5 (early-cycle VPCs). Partition of ventricular ectopic frequency (grades 1 and 2) was based on a mean VPC density of 10 or more per 1,000 beats.

All deaths during the follow-up period were from cardiac causes. Classification of the type of death was based on evaluation of the state of circulation immediately before death, as described by Hinkle et al.[11] Accordingly, sudden death was defined as an abrupt, fatal disorder of cardiac rhythm in a patient whose cardiac performance, until that moment, had been adequate to sustain peripheral circulation. Circulatory failure death was defined as progressively impaired cardiac mechanical performance, with some time elapsing before ultimate cessation of the pulse and respiration.

Survival estimates were calculated using the Kaplan-Meier life-table technique, and comparisons were made using the log-rank test with and without stratification.[12] The comparability of mean group characteristics was evaluated by an unpaired Student *t* test or by the Wilcoxon rank-sum test, as appropriate. Arrhythmia prevalence rates were examined by chi-square analysis with Yates' correction. Values are expressed as mean ± standard deviation.

Results

The overall mortality was 45% (14 of 31) during the follow-up period. The survival was 51% at 12 months and 19% at 25 months. Twelve patients died suddenly and 2 died in circulatory failure.

Arrhythmias in dilated cardiomyopathy: A mean VPC frequency of 10 or more per 1,000 beats occurred in 39% (12 of 31) of our patients, while multiform VPCs were found in 87% (27 of 31). Ventricular couplets were present in 65% (20 of 31), VPC salvos or ventricular tachycardia in 39% (12 of 31), and early-cycle forms in 6% (2 of 31).

According to peak ventricular arrhythmia grade, 71% (22 of 31) of all patients had complex ventricular arrhythmias (Lown grades 4 or 5), including 29% (9 of 31) with VPC couplets, 35% (11 of 31) with VPC salvos or ventricular tachycardia and 6% (2 of 31) with early-cycle forms as the most advanced arrhythmia grade. Brief or sustained supraventricular arrhythmias were seen in 58% (18 of 31) of the patients.

Arrhythmia subgroups and survival: The patients were grouped according to complexity of ventricular arrhythmias. Nine patients had peak Lown grades 1 to 3 arrhythmia (simple ventricular arrhythmia subgroup) and 22 patients had peak Lown grade 4 or 5 arrhythmia (complex ventricular arrhythmia subgroup). Striking mortality distinction was apparent with arrhythmia stratification (Fig. 1): mortality was 11% (1 of 9) in the simple ventricular arrhythmia subgroup and 59% (13 of 22) in the complex ventricular arrhythmia subgroup ($p < 0.025$ by log-rank test). Specifically, the mortality was 67% (6 of 9) in patients with VPC couplets as their peak ventricular arrhythmia grade, 55% (6 of 11) for patients with ventricular tachycardia and 50% (1 of 2) for those with early-cycle forms.

Because the inclusion of Lown class 5 as a complex ventricular arrhythmia may not be applicable in this population, our data were reanalyzed after reclassifying the 2 patients in Lown class 5 according to their next

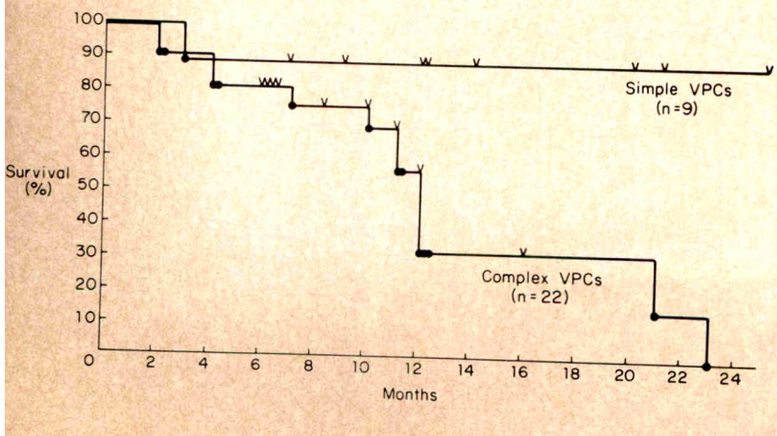

FIGURE 1. Kaplan-Meier survival curves in patients with dilated cardiomyopathy and peak Lown grade of 1 to 3 and 4A or higher. These curves are significantly different ($p < 0.025$) by the log-rank test. Survivors are denoted by **arrowheads** and nonsurvivors by **closed circles.** VPCs = ventricular premature complexes.

highest ventricular arrhythmia complexity grade. This had no effect on the significance of mortality differences between the simple and complex ventricular arrhythmia subgroups ($\chi^2 = 6.25$, $p < 0.025$).

Comparability of arrhythmia subgroups: Hemodynamic, clinical and neurohumoral summary profiles of subgroups based on arrhythmia complexity are shown in Table III. The only variable that was significantly different between the simple and complex arrhythmia patients was mean pulmonary capillary wedge pressure, which was 14 mm Hg in the simple ventricular arrhythmia subgroup and 22 mm Hg in the complex ventricular arrhythmia subgroup. However, analysis of survival distributions with respect to an elevated wedge pressure (defined as greater than 18 mm Hg) revealed no significantly excess mortality associated with high filling pressures ($\chi^2 = 1.44$, p = not significant [NS]). Further, comparing survival distributions of simple and complex ventricular arrhythmia subgroups when stratified for the presence of an elevated wedge pressure indicated a persistent trend toward a higher mortality in the complex arrhythmia subgroup ($\chi^2 = 2.03$, $0.10 < p < 0.15$).

The specific effects of wedge pressure and ventricular arrhythmias on mortality are shown in Table IV. Among patients with simple VPCs, the 1 patient who died had a pulmonary capillary wedge pressure greater than 18 mm Hg and a cardiac index of 1.00 liter/min/m^2, the lowest value of any patient in the study. However, in patients with complex ventricular ectopy, the mortality was the same in patients with high and those with low pressures (59% and 60%, respectively). Findings were also comparable when wedge pressure was partitioned at 16 mm Hg (61% vs 50%) or at 20 mm Hg (60% and 57%). Similarly, the higher mortality associated with complex ventricular arrhythmias remained significant when patients were stratified for age (partitioned at 60 years, $p < 0.05$) and cardiac index (partitioned at 2.0 liters/min/m^2, $p < 0.025$).

Arrhythmias in etiologic subgroups: Sixteen patients had ischemic DC and 15 had nonischemic DC. No

TABLE IV Dilated Cardiomyopathy: Effect of Ventricular Arrhythmias and Pulmonary Wedge Pressure on Mortality

	Ventricular Arrhythmias	
	Simple	Complex
PWP ≤18 mm Hg	0% (0/16)	60% (3/5)
PWP >18 mm Hg	33% (1/3)	59% (10/17)

PWP = pulmonary wedge pressure.

significant frequency or complexity differences between subgroups were found with respect to non–mutually exclusive categories of ventricular arrhythmias (Fig. 2) or peak Lown grade (Fig. 3). Sustained supraventricular arrhythmias (atrial fibrillation, flutter and sustained atrial tachycardia) occurred in 25% (4 of 16) of patients with ischemic DC and in 20% (3 of 15) of patients with ischemic DC (NS).

Etiologic subgroups and survival: Survival distributions were also drawn to examine the effect of etiology on mortality in DC subgroups with comparable arrhythmias. The 16 patients with ischemic DC and 15 with nonischemic DC were comparable by all hemodynamic, neurohumoral and historical variables except for age (Table V). Patients with ischemic DC were significantly older than those with nonischemic DC (62 vs 50 years, $p < 0.01$). The 1-year mortality was 44% in patients with nonischemic DC and 54% in patients with ischemic DC by Kaplan-Meier life-table analysis. Log-rank analysis of these survival distributions with stratification for increased age revealed no significant differences during the follow-up period ($\chi^2 = 0.42$, NS).

Comparison of survivors and nonsurvivors: Population profiles and hemodynamic and neurohumoral findings in the survivors and nonsurvivors were compared to determine if any characteristic other than ventricular arrhythmia complexity could identify patients most likely to die. No significant difference between survivors and nonsurvivors was found for age or

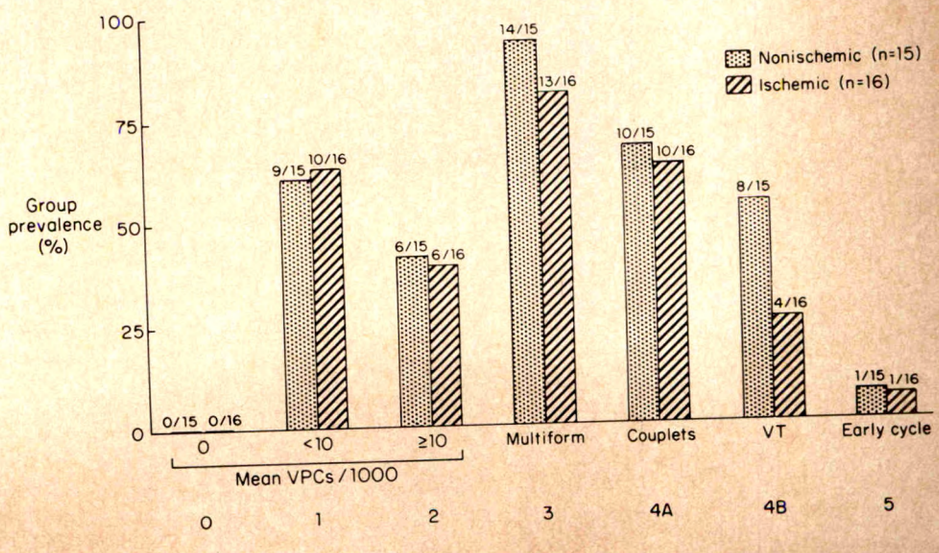

FIGURE 2. Ventricular arrhythmias in patients with ischemic and nonischemic dilated cardiomyopathy, expressed as the group prevalence of ventricular arrhythmia frequency and complexity characteristics. Each patient must appear once in the appropriate mean ventricular premature complex (VPC) density category. Each patient may also be represented in as many complexity categories as applicable, which include multiform ventricular premature complexes, couplets, ventricular tachycardia (VT) and early-cycle forms. The lower numbers refer to the Lown category corresponding to each frequency or complexity characteristic. Unlike the mutually exclusive hierarchy of the Lown scoring system, however, in this display all arrhythmias are represented according to their actual prevalence.

TABLE V Hemodynamic and Neurohumoral Profiles of Patients with Ischemic and Nonischemic Dilated Cardiomyopathy

	Ischemic	Nonischemic	p Value
Age (yr)	62 ± 10	50 ± 11	p <0.01
Sex (M/F)	13/3	12/3	NS
NYHA functional class	3.1 ± .7	3.1 ± .7	NS (W)
% on antiarrhythmic therapy	19% (3/16)	33% (5/15)	NS
Mean arterial pressure (mm Hg)	84 ± 12	86 ± 13	NS
Pulmonary capillary wedge pressure (mm Hg)	20 ± 9	20 ± 9	NS
Cardiac index (liters/min/m^2)	1.89 ± .56	2.02 ± .44	NS
Systemic vascular resistance (dynes cm s^{-5})	1,872 ± 644	1,697 ± 379	NS
Norepinephrine level (pg/ml)	624 ± 398	562 ± 300	NS
Plasma renin activity (ng/ml/hour)	10.7 ± 14.8	13.4 ± 16.4	NS (W)

NS = not significant; NYHA = New York Heart Association; W = Wilcoxon rank-sum test.

sex. Mean cardiac index (1.99 vs 1.90 liters/min/m^2), mean arterial pressure (86 vs 83 mm Hg), pulmonary capillary wedge pressure (17 vs 23 mm Hg) and systemic vascular resistance (1,796 vs 1,799) were not significantly different in survivors and nonsurvivors. There was also no significant difference in utilization of antiarrhythmic medications (24% vs 29%), mean functional class rating (2.9 vs 3.4), plasma renin activity (11.9 vs 12.2 ng/ml/hour) and plasma norepinephrine levels (500 vs 686 pg/ml) between survivors and nonsurvivors.

Discussion

Our data demonstrate that complex ventricular arrhythmias are strong predictors of cardiac death in patients with severe ischemic and nonischemic DC and suggest that the excess mortality risk conferred by complex ventricular arrhythmias is not totally dependent upon an association with poor ventricular function. These findings have important implications for risk stratification in heart failure intervention trials.

Our survival data agree with previous reports which have shown a high mortality in patients with DC.[3,4] A recent study of 182 patients with severe heart failure secondary to ischemic and nonischemic disease revealed a 66% 1-year survival,[3] which is similar to the 51% 1-year survival in our patients. Fuster et al[5] found similar results in 104 patients with idiopathic cardiomyopathy. In an earlier report by Hamby et al,[13] complex ventricular arrhythmias were frequently observed in patients with nonischemic cardiomyopathy, but prognosis was more closely related to the extent of failure than to arrhythmias.

Higher mortality in patients with congestive heart failure who have ventricular tachycardia were reported by Graboys et al[14] and Follansbee et al.[15] Meinertz et al[8] described an independent association between the frequency of VPC couplets and salvos and sudden death in patients with idiopathic DC. These findings are confirmed and extended by our study. In contrast, Huang et al[16] found no correlation between the presence of ventricular tachycardia and short-term prognosis in idiopathic cardiomyopathy. However, their 9% mortality during a mean follow-up period of 34 months is in sharp contrast to our 45% mortality during a mean follow-up period of 14 months. The low death rate found by Huang et al may have limited insights regarding predictors of mortality.

Wilson et al[7] reported that short-term survival in severe congestive heart failure was related to both functional status and the presence of 5 or more consecutive VPCs, but suggested that functional class was the only independent predictor of mortality. However, ventricular tachycardia and poor functional class were found significantly predictive of death only during the first 4 months of follow-up in that study. In contrast, we found no significant difference between the survival curves of patients in functional class IV compared with all other subjects. Moreover, when patients in functional

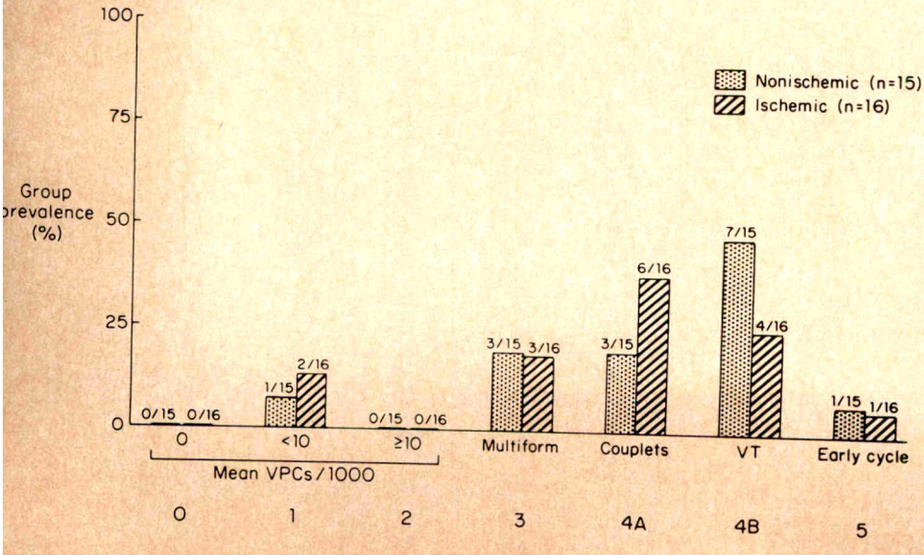

FIGURE 3. Peak grading of ventricular arrhythmias in patients with ischemic and nonischemic dilated cardiomyopathy. The ventricular arrhythmia frequency and complexity characteristics are as described in Figure 2. However, in this display each patient is represented only once, in the most advanced applicable Lown category. VPCs = ventricular premature complexes; VT = ventricular tachycardia.

class IV were eliminated from evaluation, the higher mortality associated with complex ventricular arrhythmias remained evident ($p < 0.025$). These contrasting findings might be explained by differences in patient selection and arrhythmia classification. Wilson et al evaluated patients with VPC couplets, triplets and 5-beat runs of ventricular tachycardia (but not early-cycle forms) as independent subgroups, rather than combining them as complex ventricular arrhythmias.

The 1-year mortality by Kaplan-Meier analysis for both patients with ischemic DC and those with nonischemic DC in our study was similar—54% and 44%, respectively. Our observation that prognosis is not markedly affected by etiology of DC confirms the experience of Wexler et al,[17] but is in contrast to data reported by Franciosa et al,[3] who found a 46% 1-year mortality among patients with ischemic DC but only a 23% mortality in patients with nonischemic DC. Although mortality differences between etiologic subgroups might be explained if cardiac function were different, their 2 groups of patients were reportedly comparable by historical and hemodynamic variables. However, ambulatory electrocardiograms were not evaluated in their population. In view of our data, differences in subgroup survival may thus reflect differences in ventricular arrhythmias in their subgroups rather than etiologic differences in natural history.

Potential limitations: Uncertainty regarding preterminal hemodynamic characteristics of patients and the nonuniformity of medical therapy after ambulatory electrocardiography are the major limitations of this study. However, vasodilator and antiarrhythmic drugs were maintained in a similar proportion of patients in the simple and complex ventricular arrhythmia populations, and further, antiarrhythmic drugs were not altered during the study. The impact of vasodilator therapy on ventricular arrhythmias in DC is unknown. Although such therapy could favorably influence hemodynamics and improve arrhythmias associated with poor ventricular function, excessive hypotension and the presence of digitalis and diuretic-induced metabolic derangements might adversely effect ventricular irritability. Despite these theoretical considerations, arrhythmias in our population did not appear to be markedly influenced by initial therapy. Supporting this is the observation that in 6 patients who underwent repeat 24-hour ambulatory electrocardiography after 1 week of vasodilator therapy, no patient changed peak Lown grade and no patient showed a significant change in mean or peak VPC frequency.

Clinical implications: These data are consistent with the hypothesis that complex ventricular arrhythmias represent an independent mortality risk factor in patients with severe DC. Further studies to identify the mechanisms of complex ventricular arrhythmias, as well as prospective antiarrhythmic trials, may be warranted in this population, particularly in a subset now identified as being at increased risk for death. However, our data should not be seen as a proposal that patients with DC undergo empiric antiarrhythmic therapy. It remains to be demonstrated that complex arrhythmias can be adequately suppressed by current therapeutics in patients with severely subnormal ventricular function. Further, the danger of potentially ineffective, or even harmful, therapy on an already compromised myocardium must be acknowledged.

Value of Image Enhancement and Injection of Contrast Medium for Right Ventricular Volume Determination by Two-Dimensional Echocardiography in Congenital Heart Disease

PETER E. LANGE, MD, PETER A. SEIFFERT, MD, FRANK PRIES, MD, ARMIN WESSEL, MD, DIETRICH G. W. ONNASCH, PhD, HANS-J. HAHNE, Dipl Math, and PAUL H. HEINTZEN, MD

To determine factors that influence the accuracy of echocardiographically estimated right ventricular volume and to improve the echocardiographic input information by applying image enhancement techniques, quantitative contrast echocardiography (4-chamber view) and biplane angiocardiography were performed in 23 children during routine diagnostic cardiac catheterization. Volumes calculated on the basis of unprocessed and processed echocardiographic cross sections (area-length method and sphere model) underestimated angiocardiographic volumes significantly ($p < 0.01$), and more so in end-diastole (50.6%) than in end-systole (35.9%). Thus, ejection fraction was significantly ($p < 0.01$) underestimated; mean values were 0.48 ± 0.12 and 0.60 ± 0.08, respectively. The best comparison between echocardiography and angiocardiography at end-diastole was achieved with the sphere model using image enhancement techniques and injection of contrast media, where $y = 0.54x - 6.8$, $r = 0.97$, $sy.x = 7.3$. Correlations, however, in which unprocessed echocardiograms were used showed only slightly less good correlations. With the 6 image-enhancement techniques, a more homogeneous structure of the image and a more distinct outline of the internal surface was achieved. The statistical error improved only slightly. The echocardiographic 4-chamber view allows right ventricular volume determination with an acceptable accuracy. Its underestimation is related to inadequate visualization of trabeculations and mainly to the models used. Application of image enhancement techniques allows easier outlining of the internal cavity surface. The advantage gained by the combination of contrast injection and image enhancement techniques does not warrant the routine central injection of available contrast material.

(Am J Cardiol 1985;55:152–157)

Information about the right ventricular (RV) functional state before and after corrective and palliative surgery for congenital heart diseases is important. Quantitative angiocardiography is regarded as the most accurate method for this acquiring such information, but it is an invasive technique. As a noninvasive method, 2-dimensional echocardiography (2-D echo) appears promising. However, quantitative studies yielded only fair results.[1–6] Exact determination of the accuracy of its echocardiographic volume by RV casts, the classic method for the assessment of angiocardiographic volume determination,[7–9] is impractical because available materials do not allow a sufficient echocardiographic visualization of an actual cross section.[1,4,10] Most studies therefore assess the accuracy by comparison with the biplane angiocardiographic method.[2–6] To determine factors that influence the accuracy of echocardiographically determined RV volume measurements and to improve the echographic input information by the application of digital image enhancement tech-

niques, quantitative contrast echocardiography (4-chamber view) and biplane angiocardiography were performed in 23 patients during routine diagnostic cardiac catheterization.

Methods

Study patients: Diagnoses of the 23 patients studied included patent ductus arteriosus (n = 2), pre- and postoperative tetralogy of Fallot (n = 3), transposition of the great arteries (n = 2), aortic stenosis and regurgitation (n = 2), ventricular septal defect and pulmonary stenosis (n = 2), atrial septal defect (n = 6), coarctation of the aorta (n = 3), pulmonary stenosis (n = 2) and no congenital heart disease (n = 1). The study included 8 patients aged 1 to 5 years, 5 aged 5 to 10 years, 4 aged 10 to 15 years and 6 aged 15 to 20 years. Thus, the age range was 1 to 20 years (mean 9) and body surface area was 0.46 to 1.90 m^2 (mean 1.10).

Data acquisition: Conventional angiocardiography (Pandoros, Siemens) and contrast 2-D echo (Roche RT 400, 2.8 and 3.5 MHz) were performed with a 6Fr or 7Fr Berman catheter inserted into the femoral vein, using a modified percutaneous Seldinger technique. Diatrizoate meglumine (Urografin®, Schering), 1 ml/kg (electrocardiogram triggered in diastole), was injected at 10 to 25 ml/s (mean 17) (Contrac®, Siemens) into the right ventricle and 5 to 10 ml cold 5% glucose or normal saline solution by hand into the right ventricle, right atrium or superior vena cava, with the patient in the supine position. Biplane angiocardiographic RV projections, as well as the echocardiographic 4-chamber view were recorded at 50 frames/s on videotape (Grundig) together with the electrocardiogram and identification number. For calibration purposes, a steel sphere of known diameter was filmed at the location occupied by the right ventricle during angiocardiography. Suspended respiration to minimize movement artifacts was achieved only in older children.

Image enhancement: For digitization of the echocardiographic series, which was stored on videotape, a 256 × 256 pixel, 8-bit gray-level matrix was used. Electrocardiographic-gated end-diastolic and end-systolic background and contrast frames were transferred to a standard digital disc (DEC RP04, 80 Mbyte) linked to a minicomputer (DEC PDP 11/40). Details of the digital image processing equipment[11] and techniques for enhancement[18] have been described. Images were chosen for further processing only if they correlated well with respect to movement of thorax and diaphragm with all other images in the group to be averaged. Details of the averaging technique are shown in Figure 1.

With reference to the electrocardiogram, 2 images around end-diastole and end-systole of 4 subsequent background and 3 of 2 subsequent contrast cardiac cycles were selected. Thus, for both cardiac phases at each location of the image, 8 background and 6 contrast echo amplitudes per pixel could be extracted for further processing. Such a set of amplitude samples was used to derive a representative gray level for each pixel of the background frames calculating: (1) mean value (MB), (2) standard deviation of the sample (SB) by calculating the square root of the mean squared deviation from the mean, and (3) median value (MED) by sorting the N = 8 amplitudes in descending order and then selecting the value at position N/2.

For contrast frames, the mean (MC), and for the 8 background plus 6 contrast frames together, the standard deviation (SBC) were calculated. For the exclusive display of contrast medium mean values were substracted: (4) SM = MC − MB, and normalized for the standard deviations, (5) SMB = SM/SB, and (6) SMC = SM/SBC (Fig. 1).

Measurements: Biplane angiocardiographic projections and the echocardiographic cross sections were assessed in a similar manner. This technique has been described.[12,13] Displayed on a television monitor, the biplane projections (steel sphere and ventricles in sinus beats) and echocardiographic cross sections were traced with an x/y coder using a resistance foil and stored on the disc of a mini computer (DEC PDP 11/60). In addition to the RV outlines, anatomically defined internal landmarks (Fig. 2) were marked and stored the same way. For calibration of the echographic image, a built-in system of defined distances was used.

Angiocardiographic RV volumes were calculated with the biplane multiple-slices method, the model volumes being corrected with factors appropriate for spatial orientation and cardiac phase.[8,9] The spatial ventricular axes between the center of the pulmonary valve ring and the apex, as well as between tricuspid valve and apex, were calculated on the basis of the respective landmarks (Fig. 2, upper panel). The mean diameter (MDA) is defined as the diameter of the sphere with the angiocardiographic volume of the right ventricle, obtained with the area-length method.

The echocardiographic volumes were calculated in 3 ways:
(1) $V = (\pi/6)\ MDE^3$, where MDE is the diameter of the circle with the area (A) of the echographic cross-section (sphere volume). (2) $V = (3/8\pi)\ A^2/TR$, where TR is the distance between the tricuspid valve (T) and the trabeculated portion (R) (area-length volume) (Fig. 2, lower panel); (3) $V = \pi/6\ TR^3$.

The difference between end-diastolic and end-systolic volume is the stroke volume and the ratio stroke volume/end-diastolic volume, the ejection fraction. To characterize the shape TR was divided by MDE.

Results

Of 35 patients who underwent angiocardiography and echocardiography, 23 were included in this study. The reasons for exclusion were premature ventricular complexes during angiocardiography in 1 patient (precluding adequate opacification of the second post-extrasystolic beat), technical malfunction of the videotape in 4 patients and inadequate contrast of the echographic RV cross section in 7 patients. Results of the regression analysis of the relation between angiocardiographic volumes as reference and the different

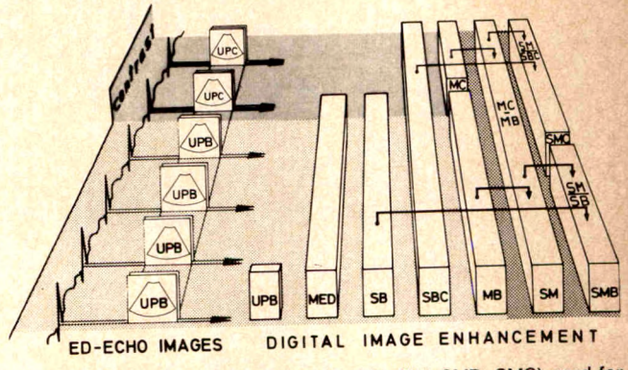

FIGURE 1. The 6 methods (MED, SB, MB, SM, SMB, SMC) used for digital enhancement of television images of 2-dimensional echocardiographic series. Contrast = images after the injection of cold normal saline solution and 5% glucose into the superior vena cava, right atrium and right ventricle; ED-ECHO = end-diastolic echocardiographic; MB = mean value of UPB; MC = mean value of UPC; MED = median value; SB = standard deviation of UPB; SBC = standard deviation of UPB plus UPC; SM = MC-MB; SMB = SM/SB; SMC = SM/SBC; UPB = unprocessed background; UPC = unprocessed contrast.

echocardiographic volumes are summarized for sphere volumes in Table I. Volumes calculated on the basis of processed as well as unprocessed echocardiographic cross-sections underestimated the angiocardiographic volumes significantly ($p < 0.01$) and significantly more ($p < 0.001$; paired t test) in end-diastole than in end-systole (Table I). Unprocessed echo underestimated the angio ejection fraction significantly ($p < 0.01$), the mean values being 0.480 ± 0.120 and 0.595 ± 0.077, respectively. The correlation was $r = 0.55$.

When angio- and echographic volumes were correlated (Table II), similar statistical errors were found for the echo volumes calculated with the sphere model as with the area-length formula, whereas the highest error was found for the volume calculated only on the basis of the long-axis TR (Fig. 2). With all image enhancement techniques, a more homogeneous structure of the image and a more distinct outline of the internal surface of the cavity was achieved (Fig. 3). When echographic and angiographic volumes were compared (Table I, Fig. 4), the lowest statistical errors were observed using the median value ($r = 0.970$) and contrast echo after normalized background subtraction using SMB ($r = 0.974$).

The shape of the echocardiographic cross section (4-chamber view, unprocessed background), expressed as the ratio TR/MDE, was slightly more circular in end-systole than in end-diastole, but this difference did not reach statistical significance (Table III). In contrast, the spatial angiocardiographic shape expressed as ratio axis pulmonary valve–apex/MDA and axis tricuspid valve–apex/MDA was significantly less spherical ($p < 0.01$) in end-systole (Table III).

Two-dimensional-echocardiographic 4-chamber views. **Top,** unprocessed background (UPB); **middle,** processed background, median value (MED); **bottom,** contrast subtraction image (SMB) after injection of cold normal saline solution into the right ventricle. Image enhancement techniques achieve more homogeneous images (**middle and bottom**). Abbreviations as in Figure 2.

Based on angiographically determined spatial anatomic landmarks, the apex moved during systole 5.5 ± 2.8 mm superior, 1.6 ± 4.6 mm to the left and 1 ± 1 mm dorsal, while the center of the pulmonary valve ring moved 8 ± 5 mm inferior, 6.3 ± 4.7 mm to the left and 6.8 ± 5.1 mm anterior. Thus, the ventricular axis pulmonary valve ring/apex tilted 4.3 ± 2.2° during systole.

Discussion

Systematic error: Our results indicate that 2-D echo underestimates angiocardiographic volumes signifi-

TABLE I Regression Analysis y = a + bx of Right Ventricular Volume Parameters (n = 23) Determined by Angiocardiography (x) and Echocardiography (y) Before and After Application of Different Image Enhancement Methods

All echocardiographic volumes were determined using the sphere model.

ANGIO = angiocardiography; Diff. = pair difference ± standard deviation; ECHO = echocardiography; EDV = end-diastolic volume; EF = ejection fraction; ESV = end-systolic volume; MB = mean value of unprocessed background; MED = median value; r = correlation coefficient; SB = standard deviation of unprocessed background; SM = mean value of unprocessed contrast − unprocessed background; SMB = SM/SB; SMC = SM/SBC; SV = stroke volume; sy.x = standard error of the estimate; UPB = unprocessed background.

TABLE II Unprocessed Echographic Versus Angiographic Volumes for 3 Echographic Models

	End-Diastole		End-Systole	
Model	r	v	r	v
Sphere	0.97	18%	0.95	24%
Area-length	0.95	24%	0.95	22%
TR^3	0.91	31%	0.79	53%

r = correlation coefficient; TR = echocardiographic long axis (Fig. 2); v = variation coefficient.

TABLE III Right Ventricular Shape Parameters (n = 23)

	Angio PA/MDA	Angio TA/MDA	Echo TR/MDE
ED	1.36 ± 0.11	1.13 ± 0.12	1.32 ± 0.15
ES	1.45 ± 0.11	1.19 ± 0.15	1.26 ± 0.13
ED-ES	−0.08 ± 0.10	−0.07 ± 0.11	0.06 ± 0.16
p Value	<0.001	<0.01	NS

ED-ES = systolic change, tested for being 0; MDA = mean diameter equal to the diameter of the sphere with the angiographic area-length volume; MDE = mean diameter equal to the diameter of the circle with echographic area; NS = not significant; PA = spatial distance pulmonary valve–apex; TA = spatial distance tricuspid valve apex; TR = distance tricuspid valve–apex in the echocardiographic cross section, as derived from landmarks (Fig. 2); other abbreviations as in Table I.

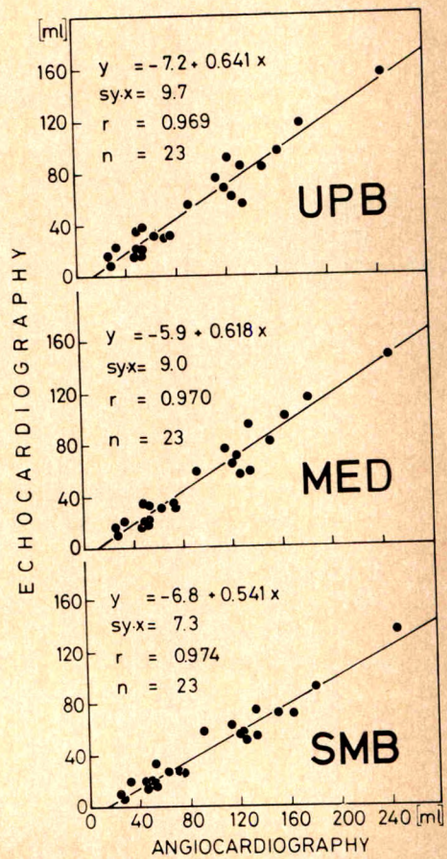

FIGURE 4. Relation between end-diastolic volumes, determined by angiocardiography and by echocardiography, using the sphere model. Application of image enhancement techniques (**middle**), as well as the additional injection of contrast media (**bottom**), achieve a more homogeneous image, allowing easier border recognition. The accuracy is, however, only minimally improved in comparison with the original image (**top**). sy.x = standard error of the estimate; other abbreviations as in Figure 1.

cantly (Table I, Fig. 4). The mean reason appears to be the limited echocardiographic input information. Calculation based on the typical triangular shaped cross section of inflow tract and trabeculated portion underestimates total RV volume if a sphere model is used (Table I, Fig. 4). Adjusting the model—a mathematical maneuver to prevent under- or overestimation—does not improve the accuracy of the method.[2,10] The input information remains unchanged. It appears to be easier and also appropriate to use a simple model like a sphere or ellipsoid and then correct the regression line to become the line of identity.

Another reason for the echocardiographic underestimation of angiocardiographic volumes is that roentgen contrast media surround the trabeculae carnea, thus including them within the angiographic outline, whereas the echocardiographic outline represents, in many instances, the innermost portions of the trabeculations, owing to the finite resolution of the echocardiographic beam. The resolution is limited laterally as well as perpendicularly to the scanning plane,[13–15] resulting in a left ventricular cavity outline that is inside the angiocardiographic border. Its visual limitations are especially obvious in the trabeculated portion of the right ventricle (Fig. 3). Only a very small part is included within the echocardiographic outline of the cavity.

Echocardiographic underestimation of the angiocardiographic volume was significantly less ($p < 0.01$) in end-systole than in end-diastole, the mean ratio echographic/angiographic volumes being 28% higher in end-systole. With the exception of the report of Silverman and Hudson,[5] such a difference has not been reported.[2,3,6] This result may be related in part to the different factors used for correction of the angiocardiographic model volumes. We are the only investigators who have used different factors for end-diastole and end-systole, the latter being approximately 15% smaller than the former.[8] In addition, the poorly visualized trabeculated portion should comprise a relatively larger area of the cross section in systole than in diastole compared with respective angiographic projections. Assessing the shape of the echocardiographic cross section, the end-diastolic/end-systolic echocardiographic information would appear to differ from angiocardiographic data. In contrast to the echocardiographic shape parameter, the angiographic parameters indicate a less spherical shape in end-systole (Table III). Little of the trabeculated portion and more of the inflow tract is visualized echographically, thus preventing quantitation of its changes during the cardiac cycle. An additional factor could be the superior systolic movement of the apex by 5° with respect to the pulmonary and tricuspid valves as well as with respect to the echocardiographic transducer. This different visualization of the right ventricle in diastole and systole is also responsible for the significant ($p < 0.001$) echographic underestimation of the angiographic ejection fraction (Table I).

The nonsimultaneous recording of angiocardiogram and echocardiogram could result in a larger angiographic volume, because flow and, presumably, RV volumes increase after injection of angiographic contrast medium into the right ventricle. Flow remains elevated at least 20 minutes after the injection of diatrizoate (Urografin).[16] This is when the echocardiographic recording was performed in all our patients.

Statistical error: The statistical errors relating echographic and angiographic volumes (Fig. 4, Table I) compare favorably with those previously reported[2–6]; they are at least as low as those found for the left ventricle.[14,17] This is surprising because the input information of the complex internal geometry obtained with the 4-chamber view is small (Fig. 3). The low statistical error (Table I, Fig. 4) indicates that the shape of the right ventricle is rather constant and that the 4-chamber view is comparably well reproducible, correcting for the different spatial orientations of the right ventricle in patients with different congenital heart diseases, a variety of which are included in this study. Attempts to increase the input information by using biplane echographic views and thus improve accuracy failed.[3,5,6,9] Standardization of these views appears to be too difficult. The gained information cannot compete with that of standard biplane angiocardiographic projections of the right ventricle. Also, reducing the input information to a single "standard dimension," as has been proposed by Bommer et al[1] on the basis of cast studies, may not be appropriate. When the area of the cross section was used to calculate RV volumes, significantly lower statistical errors resulted (Tables I and II) than if only 1 diameter (the long-axis TR) was used (Fig. 2, Table II). This finding suggests that such a standard dimension of the 4-chamber view varies more than the cross-sectional area.

Background images: The "noisy" appearance and the often poor border definition of the RV endocardial surface are limitations typical for 2-D echo images. To improve these limitations, different image enhancement techniques were applied. With use of all techniques, a homogeneous structure of the image and a more distinct outline of the internal surface of the RV cavity could be achieved in most cases (Fig. 3). The location of this internal border, however, is different for the 3 methods. Correspondingly, the calculated volumes are different (Table I). If such enhancement techniques are used in order to make outlining the RV cavity easier and faster, the same statistical method should be applied. In terms of statistical error, the median value offers the highest correlation coefficient and the lowest scatter of data (Table I, Fig. 4).

Contrast echocardiography and digital subtraction: Contrast echo to outline the RV inner surface is only useful in conjunction with background subtraction techniques (Fig. 1). Our group[18,19] and other investigators[20] have demonstrated the feasibility of this technique. Tracing the outline becomes easier and faster than it is after the application of background enhancement techniques. The achieved decrease of the statistical error, however, was only slight (Table I). The main reason was probably the contrast agents used, which did not distribute homogeneously enough.

Contrast echocardiographic volumes probably were consistently lower than noncontrast echocardiographic volumes (Table I), because in many regions the contrast

agent does not reach the internal surface of trabeculae carnae. Standardized bubbles may improve or abolish these disadvantages.

Acknowledgment: We thank Roswitha Bestehev and Iśa Schulze Brexel for their continuous and invaluable assistance.

CME TEST #19

Baseline Rest Electrocardiographic Abnormalities, Antihypertensive Treatment, and Mortality in the Multiple Risk Factor Intervention Trial*

The University of Alabama School of Medicine designates this continuing medical education activity for 1 credit hour in Category 1 of the Physician's Recognition Award of the American Medical Association. Answers are to be marked on the instruction sheet on page A165.

1. In the Multiple Risk Factor Intervention Trial (MRFIT), coronary artery disease (CAD) and total death rates were not anticipated to be so:
   a) high in the special intervention (SI) group
   b) high in the usual care (UC) group
   c) considerably low in both groups
   d) considerably high in both groups

2. Exercise testing was performed in the MRFIT only at the:
   a) prescreening of the study
   b) third screening
   c) second screening
   d) first screening

3. Men who were taking medicine and had a diastolic blood pressure of 90 mm Hg were assigned to:
   a) reach a goal of 80 mm Hg
   b) reach a goal of 50 mm Hg
   c) reach a goal of 89 mm Hg
   d) reach a goal of 70 mm Hg

4. With SI patients, serum levels of potassium were determined and reported:
   a) every 4 months
   b) every other visit
   c) every third visit
   d) none of the above

5. CAD deaths were subclassified as documented myocardial infarction and:
   a) sudden death within 60 minutes, or between 1 and 24 hours of symptom onset, without documented myocardial infarction
   b) congestive heart failure due to CAD
   c) death associated with surgery for CAD
   d) all of the above

6. MRFIT was not designed to:
   a) estimate the effect of a multifactor intervention program on CAD mortality
   b) estimate effect of individual intervention
   c) compare SI groups with UC groups
   d) do all the above

7. As of February 28, 1982, among UC men there were:
   a) 88 CAD deaths with electrocardiographic (ECG) abnormalities
   b) 88 CAD deaths without ECG abnormalities
   c) 68 CAD deaths with ECG abnormalities
   d) 68 CAD deaths without ECG abnormalities

8. Thirty-nine percent of ECG abnormalities were:
   a) high R waves
   b) negative T waves
   c) conduction defects
   d) left-axis deviation

9. Among men who had an exercise electrocardiogram, the percent with abnormal electrocardiographic responses during or right after the exercise test, using computer criteria, was:
   a) 8.2%
   b) 18%
   c) 12.2%
   d) 26%

10. In hypertensive men in the SI group, the strength of the association between reduction in the serum cholesterol level and CAD mortality:
    a) was higher with presence of ECG abnormalities
    b) was higher with absence of ECG abnormalities
    c) did not differ significantly with or without ECG abnormalities
    d) does not correlate

***This article appears on page 1 of this issue.**

Introducing TONOCARD®

(TOCAINIDE HCl | MSD)

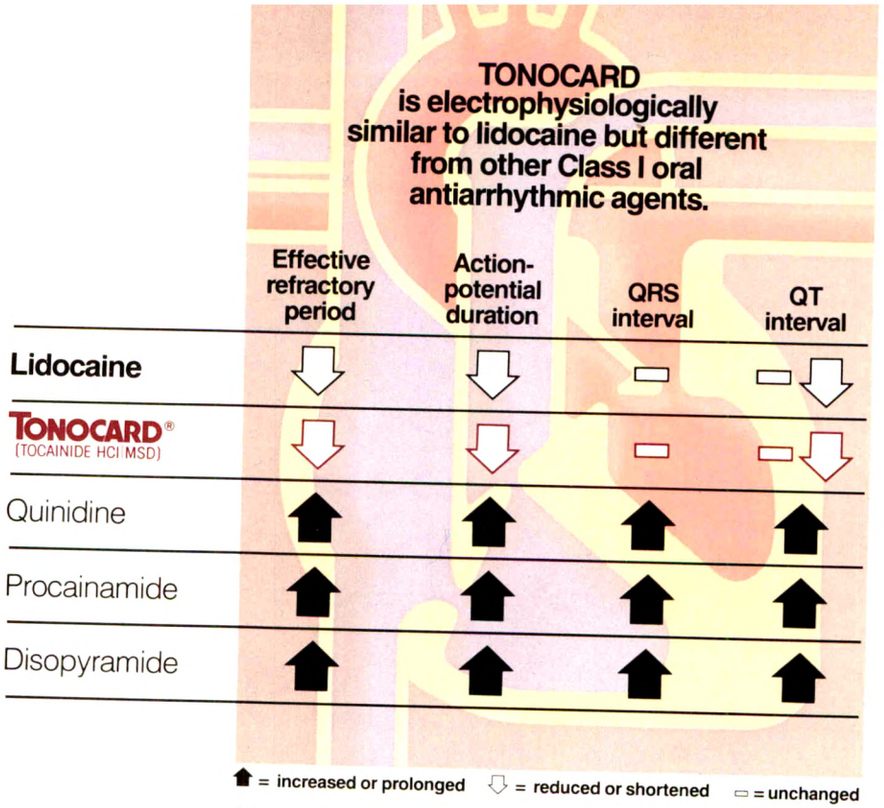
a new oral agent for the suppression of symptomatic ventricular arrhythmias

Like lidocaine.

But it's oral.

For a Brief Summary of Prescribing Information, please see last page of this advertisement.

MSD
MERCK



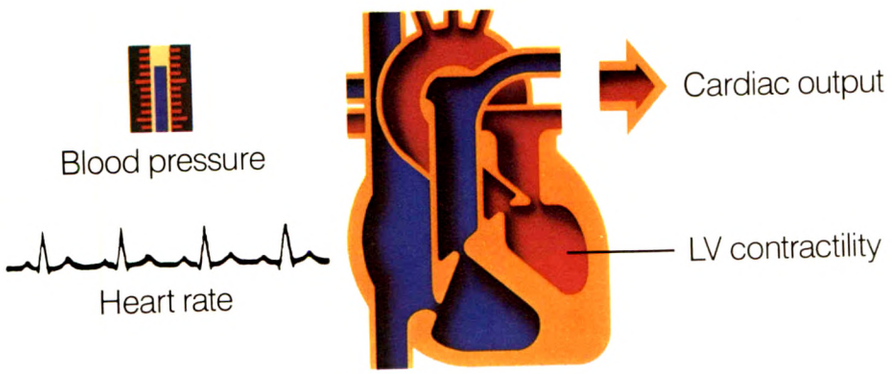
Adapted from Braunwald, E.: Pharmacologic treatment of cardiovascular disorders, in *Harrison's Principles of Internal Medicine*, ed. K. J. Isselbacher et al., 9th ed., New York, McGraw-Hill Book Company, 1980, pp. 1068-1069. Data derived from animal and human studies.

☐ Patients who respond to lidocaine also respond to TONOCARD in a majority of cases. Failure to respond to lidocaine usually predicts failure to respond to TONOCARD, but there are exceptions.

Therapeutically, it acts like lidocaine.

Clinical cardiac parameters were usually unchanged in well-compensated patients studied.

- In a long-term study of 72 post-myocardial infarction patients, TONOCARD (400 mg q 8 h) did not produce clinically significant changes in blood pressure, heart rate, or LV contractility.



- In catheterization studies, TONOCARD usually produced a small degree of depression in left ventricular function, but there were usually no changes in cardiac output or clinical evidence of increasing congestive heart failure.

TONOCARD has been used safely in patients with acute myocardial infarction and various degrees of congestive heart failure. It has, however, a small negative inotropic effect and can increase peripheral resistance slightly.

- TONOCARD should be used cautiously in patients with known heart failure or minimal cardiac reserve, particularly if a beta blocker is given as well, because of the potential for aggravating the degree of heart failure.

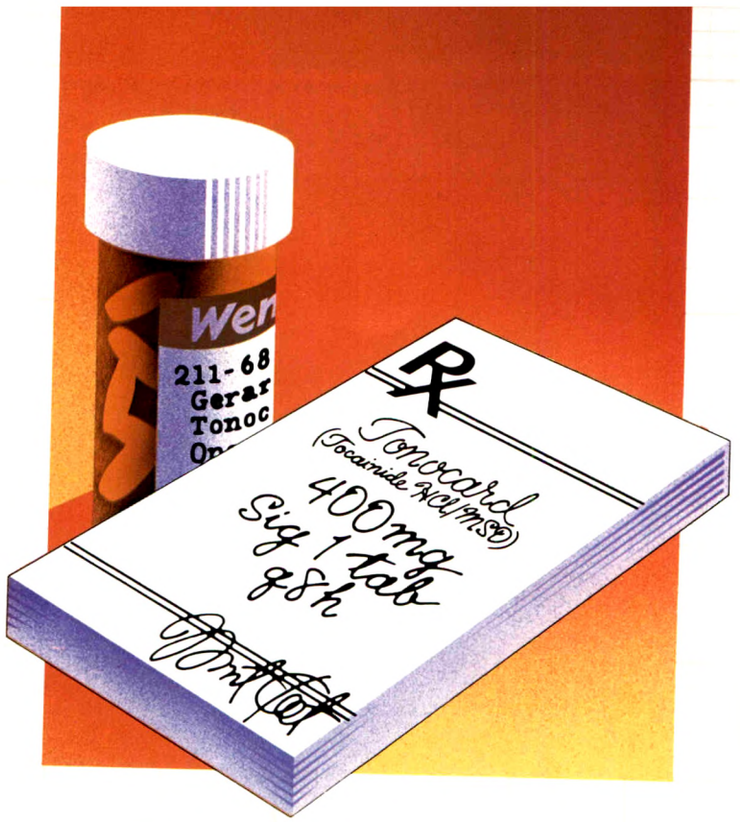
TONOCARD is contraindicated in patients who are hypersensitive to this product or to local anesthetics of the amide type and in patients with second- or third-degree atrioventricular block in the absence of an artificial ventricular pacemaker.

For a Brief Summary of Prescribing Information, please see last page of this advertisement.

But it's oral.

new TONOCARD® (TOCAINIDE HCl | MSD)

MSD
MERCK



☐ Simple initial q 8 h dosage.

Unlike lidocaine, it's useful for maintenance therapy.

Recommended initial dosage is 400 mg every 8 hours; patients should then be carefully titrated on the basis of antiarrhythmic response and tolerance, both of which are dose-related. The usual adult dosage is between 1200 and 1800 mg/day, divided in three doses. Doses beyond 2400 mg have been administered infrequently. Patients who tolerate the t.i.d. regimen may be tried on a twice-daily regimen with careful monitoring. Some patients, particularly those with renal or hepatic impairment, may be treated with less than 1200 mg/day.

To help alleviate the most common adverse reactions, TONOCARD may be given with food (without affecting the extent of its bioavailability), the dosage reduced, or therapy discontinued.

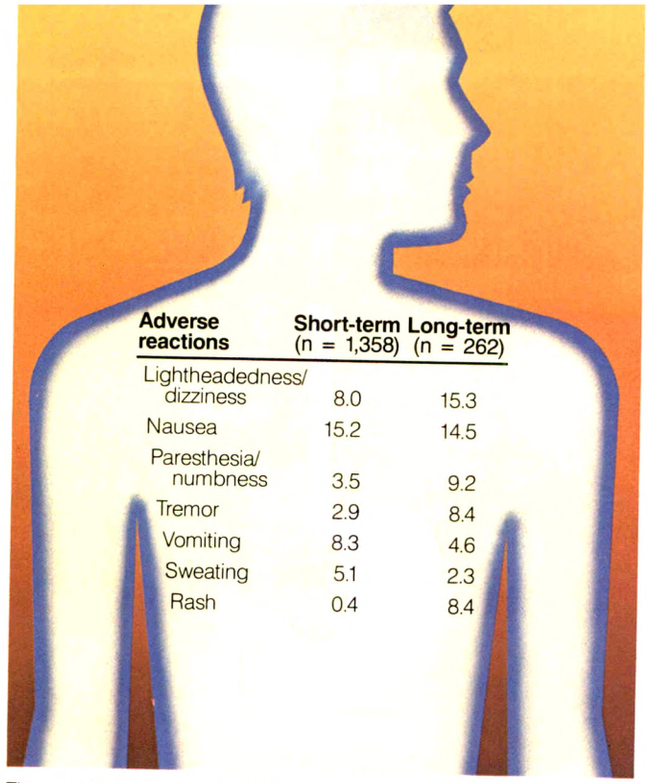
Like other antiarrhythmics, tocainide has not been shown to prevent sudden death in patients with serious ventricular ectopic activity, and also, like other antiarrhythmics, it has potentially serious adverse effects including the ability to worsen arrhythmias. It is therefore essential that each patient given tocainide be evaluated electrocardiographically and clinically prior to and during tocainide therapy to determine whether the response to tocainide supports continued treatment.

For a Brief Summary of Prescribing Information, please see last page of this advertisement.

Because it's oral.

new TONOCARD®
(TOCAINIDE HCl | MSD)

MSD
MERCK



Reactions leading to therapy discontinuation occurred in 21% of patients in long-term (2 to 6 months) controlled trials.

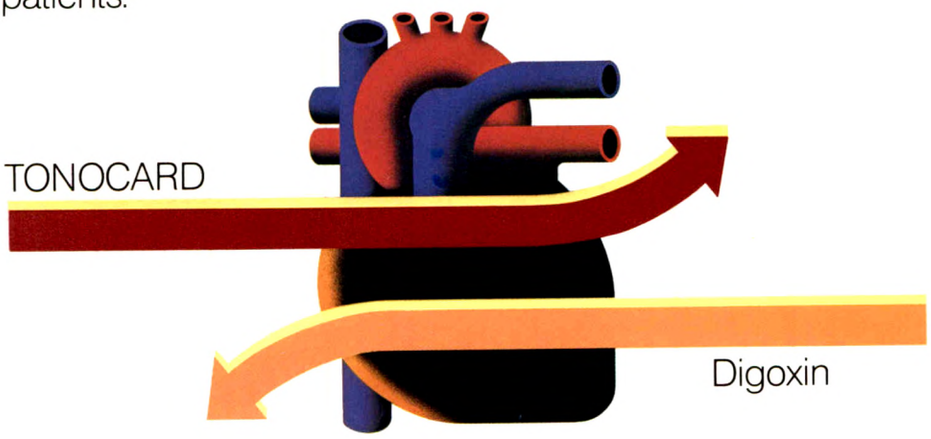
The most frequently reported adverse reactions, expressed as a percentage of patients receiving TONOCARD® (Tocainide HCl, MSD) in short-term and long-term controlled clinical trials.

- ☐ These adverse reactions were generally mild, transient, dose-related, and reversible with reduction in dosage, by taking the drug with food, or by therapy discontinuation.
- ☐ Tremor may be useful as a clinical indicator that the maximum dose is being approached.

CNS and GI reactions are common...

No interaction seen with digoxin.

- ☐ In specific interaction studies and open clinical studies with digoxin and TONOCARD, no clinically significant interaction was seen.
- ☐ TONOCARD is equally effective in digitalized and nondigitalized patients.



Other antiarrhythmics, anticoagulants, and diuretics were given with TONOCARD in open studies, without evidence of clinically significant interaction.

Beta blockers have been used with TONOCARD in open studies, without evidence of clinically significant interaction.

- ☐ However, in a specific interaction study, TONOCARD and metoprolol had additive effects on wedge pressure and cardiac index.

Caution should be exercised in the use of multiple-drug therapy.

Caution should be used in the institution or continuation of antiarrhythmic therapy in the presence of signs of increasing excessive depression of cardiac conductivity.

For a Brief Summary of Prescribing Information, please see last page of this advertisement.

but usually mild and manageable.

new **TONOCARD®**
(TOCAINIDE HCl | MSD)

MSD

new TONOCARD® (TOCAINIDE HCl | MSD)

An oral analog of lidocaine for the suppression of symptomatic ventricular arrhythmias

TONOCARD®
(Tocainide HCl | MSD)

Like other antiarrhythmics, tocainide has not been shown to prevent sudden death in patients with serious ventricular ectopic activity, and also, like other antiarrhythmics, it has potentially serious adverse effects, including the ability to worsen arrhythmias. It is therefore essential that each patient given tocainide be evaluated electrocardiographically and clinically prior to, and during, tocainide therapy to determine whether the response to tocainide supports continued treatment.

CONTRAINDICATIONS: Patients who are hypersensitive to this product or to local anesthetics of the amide type.

Patients with second or third degree atrioventricular block in the absence of an artificial ventricular pacemaker.

WARNINGS: ***Blood Dyscrasias:*** Leukopenia, agranulocytosis, hypoplastic anemia, and thrombocytopenia, possibly drug related, have been reported in patients receiving TONOCARD. Many of these events occurred in patients who were seriously ill and who were receiving concomitant drugs. Patients should be instructed to promptly report the development of bruising or bleeding and any signs of infection such as fever, sore throat, or chills. Periodic blood counts are recommended, particularly during the first six months of therapy. If any of these hematologic disorders is identified, TONOCARD should be discontinued and appropriate treatment should be instituted if necessary. Blood counts usually return to normal within one month of discontinuation (see ADVERSE REACTIONS).

Acceleration of Ventricular Rate: Acceleration of ventricular rate occurs infrequently when antiarrhythmics are administered to patients with atrial flutter or fibrillation (see ADVERSE REACTIONS).

PRECAUTIONS: *General:* ***Pulmonary Fibrosis:*** Pulmonary fibrosis, pneumonitis, alveolitis, pulmonary edema, and pneumonia, possibly drug related, have been reported in patients receiving TONOCARD. Many of these events occurred in patients who were seriously ill. The experiences are usually characterized by bilateral infiltrates on x-ray and are frequently associated with dyspnea and cough. Fever may or may not be present. Patients should be instructed to promptly report the development of any pulmonary symptoms such as exertional dyspnea, cough or wheezing. Chest x-rays are advisable at that time. If these pulmonary disorders develop, TONOCARD should be discontinued (see ADVERSE REACTIONS).

In patients with known heart failure or minimal cardiac reserve, TONOCARD should be used with caution because of the potential for aggravating the degree of heart failure.

Caution should be used in the institution or continuation of antiarrhythmic therapy in the presence of signs of increasing depression of cardiac conductivity.

In patients with severe liver or kidney disease, the rate of drug elimination may be significantly decreased (see DOSAGE AND ADMINISTRATION).

Since antiarrhythmic drugs may be ineffective in patients with hypokalemia, the possibility of a potassium deficit should be explored and, if present, the deficit should be corrected.

Like all other oral antiarrhythmics, TONOCARD has been reported to increase arrhythmias in some patients (see ADVERSE REACTIONS).

Drug Interactions: Specific interaction studies with digoxin and metoprolol have been conducted, no clinically significant interaction was seen with digoxin, but tocainide and metoprolol had additive effects on wedge pressure and cardiac index. TONOCARD has also been used in open studies with digitalis, beta-blocking agents, other antiarrhythmic agents, anticoagulants, and diuretics, without evidence of clinically significant interactions. Nevertheless, caution should be exercised in the use of multiple drug therapy.

TONOCARD is equally effective in digitalized and nondigitalized patients. In 17 patients with refractory ventricular arrhythmias on concomitant therapy, serum digoxin levels (11 ± 0.4 ng/mL) remained in the expected normal range (0.5-2.5 ng/mL) during tocainide administration.

Pregnancy: Pregnancy Category C: In a teratogenicity study in rabbits, tocainide was administered orally at doses of 25, 50, and 100 mg/kg/day (about 1 to 4 times the usual human dose). No evidence of a drug-related teratogenic effect was noted; however, these doses were maternotoxic and produced a dose-related increase in abortions and stillbirths. In a teratogenicity study in rats, an oral dose of 300 mg/kg/day (about 12 times the usual human dose) showed no evidence of treatment-related fetal malformations, but maternotoxicity and an increase in fetal resorptions were noted. An oral dose of 30 mg/kg/day (about twice the usual human dose) did not produce any adverse effects.

In reproduction studies in rats at maternotoxic oral doses of 200 and 300 mg/kg/day (about 8 and 12 times the usual human dose, respectively), dystocia, and delayed parturition occurred which was accompanied by an increase in stillbirths and decreased survival in offspring during the first week postpartum. Growth and viability of surviving offspring were not affected for the remainder of the lactation period.

TONOCARD®
(Tocainide HCl | MSD)

There are no adequate and well-controlled studies in pregnant women. TONOCARD should be used during pregnancy only if the potential benefit justifies the potential risk to the fetus.

Nursing Mothers: It is not known whether tocainide is secreted in human milk. Because many drugs are secreted in human milk and because of the potential for serious adverse reactions in nursing infants from TONOCARD, a decision should be made whether to discontinue nursing or to discontinue the drug, taking into account the importance of the drug to the mother.

Pediatric Use: Safety and effectiveness in children have not been established.

ADVERSE REACTIONS: TONOCARD commonly produces minor, transient, nervous system and gastrointestinal adverse reactions, but is otherwise generally well tolerated. TONOCARD has been evaluated in both short-term (n = 1,358) and long-term (n = 262) controlled studies as well as a compassionate use program. Dosages were lower in most of the controlled studies (1200 mg/day) and higher in the compassionate use program (1800 mg and more). In long-term (2-6 months) controlled studies, the most frequent adverse reactions were lightheadedness/dizziness (15.3 percent), nausea (14.5 percent), paresthesia/numbness (9.2 percent), and tremor (8.4 percent). These reactions were generally mild, transient, dose-related and reversible with a reduction in dosage, by taking the drug with food, or by therapy discontinuation. Tremor, when present, may be useful as a clinical indicator that the maximum dose is being approached. Adverse reactions leading to therapy discontinuation occurred in 21 percent of patients in long-term controlled trials and were usually related to the nervous system or gastrointestinal system.

Adverse reactions occurring in greater than one percent of patients from the short-term and long-term controlled studies appear in the following table:

	Percent of Patients Controlled Studies	
	Short-term (n = 1,358)	Long-term (n = 262)
NERVOUS SYSTEM		
Lightheadedness/dizziness/vertigo/giddiness	8.0	15.3
Paresthesia/numbness	3.5	9.2
Tremor/quivering/tremulousness	2.9	8.4
Confusion/disorientation/hallucinations	2.1	2.7

An additional group of about 2,000 patients has been treated in a program allowing for the use of TONOCARD under compassionate use circumstances. These patients were seriously ill with the large majority on multiple drug therapy, and comparatively high doses of TONOCARD were used. Fifty-four percent of the patients continued in the program for one year or longer, and 12 percent were treated for longer than three years, with the longest duration of therapy being nine years. Adverse reactions leading to therapy discontinuation occurred in 12 percent of patients (usually central nervous system effects or rash). A tabulation of adverse reactions occurring in one percent or more of patients follows:

Adverse reactions occurring in less than one percent of patients in either the controlled studies or the compassionate use program are as follows:

Nervous System: Coma, convulsions/seizures, depression, psychosis, mental change, agitation, altered taste/smell, difficulty concentrating, diplopia, dysarthria, impaired memory, increased stuttering/slurred speech, insomnia/sleeping disturbance, local anesthesia, nightmares, thirst, weakness, myasthenia gravis.

Gastrointestinal System: Abdominal pain/discomfort, constipation, dysphagia, gastrointestinal symptoms (including dyspepsia).

Cardiovascular System: Ventricular fibrillation, extension of acute myocardial infarction, cardiogenic shock, angina, AV block, hypertension, increased QRS duration, pleurisy/pericarditis, prolonged QT interval, right bundle branch block, syncope, vaso-vagal episodes, cardiomegaly, sinus arrest.

Pulmonary System: Respiratory arrest, pulmonary edema, pulmonary embolism, pulmonary fibrosis, alveolitis, pneumonia, pneumonitis, dyspnea.

Other: Hematologic disorder (agranulocytosis, hypoplastic anemia, anemia, leukopenia, thrombocytopenia), increased ANA, urinary retention, polyuria/increased diuresis, alopecia, cinchonism, claudication, cold extremities, dry mouth, earache, edema, fever, hiccups, itching, leg cramps, malaise, metallic/menthol taste, muscle twitching/spasm, neck pain, pain radiating from neck, pallor/flushed face, pressure on shoulder, yawning.

Leukopenia, agranulocytosis, hypoplastic anemia, and thrombocytopenia, possibly drug related, have been reported (0.10 percent) in patients receiving TONOCARD in controlled trials and the compassionate use program. These hematologic disorders usually occurred after 2-12 weeks of therapy and two patients died. These events usually occurred in seriously ill patients who were receiving concomitant drugs known to be associated with hematologic disorders (see WARNINGS).

Pulmonary fibrosis, pneumonitis, alveolitis, pulmonary edema, and pneumonia, possibly drug related, have been reported in patients receiving TONOCARD. The incidence of pulmonary fibrosis was 0.03 percent in controlled trials and the compassionate use program. These events usually occurred in seriously ill patients. Symptoms of these pulmonary disorders and/or x-ray changes usually occurred following 3-18 weeks of therapy and two patients died (see PRECAUTIONS).

HOW SUPPLIED: Tablets containing 400 mg or 600 mg in bottles of 100 and unit-dose packages of 100.

Magnitude and Implications of Spontaneous Hemodynamic Variability in Primary Pulmonary Hypertension

STUART RICH, MD, GILBERT E. D'ALONZO, DO, DAVID R. DANTZKER, MD, and PAUL S. LEVY, ScD

The pulmonary artery (PA) pressure and pulmonary resistance at rest have been noted to vary spontaneously in patients with primary pulmonary hypertension. To evaluate this variation, in 12 patients (8 women, 4 men, aged 43 ± 13 years), hourly measurements were made for 6 consecutive hours of heart rate, systemic and PA pressures, cardiac output, systemic and pulmonary resistance. After these baseline measurements the patients were tested with hydralazine and nifedipine therapy. Spontaneous variability in pulmonary pressures and resistances occurred in each patient, with the amount of variation (coefficient of variation) in PA pressure averaging 8% and in total pulmonary resistance 13% over the 6 hours. The patients with the most variability in mean PA pressure also had the most variability in cardiac output ($r = 0.69$, $p = 0.02$). Variability also correlated with the severity of the disease, as the patients with the highest total pulmonary resistances also had the most variation for that factor ($r = 0.91$, $p < 0.01$). The amount of variability did not correlate, however, with the acute response to either hydralazine or nifedipine administration. Based on the average coefficients of variation in these 12 patients, estimates were obtained of the percent change needed for an observed change to be attributed to a drug effect with 95% confidence. From these estimates, it was projected that for a single patient, a mean change in pulmonary resistance of 36% or a mean change in PA pressure of 22% would be required in order to attribute the changes to a drug effect. Thus, spontaneous hemodynamic variability is a common phenomenon in patients with primary pulmonary hypertension and may account for substantial changes in PA pressure and pulmonary resistance at rest.

(Am J Cardiol 1985;55:159–163)

Vasodilator drugs have been reported to lower the pulmonary artery (PA) pressure and pulmonary vascular resistance in patients with primary pulmonary hypertension (PPH).[1–5] However, PA pressure and pulmonary resistance may change spontaneously, without any drug intervention.[6] The implications of this spontaneous variability are not clear, nor is it known if it is a common or unusual phenomenon. We monitored the pulmonary and systemic central hemodynamics of 12 patients with PPH every hour for 6 consecutive hours to determine their magnitude of variation. We then administered vasodilator drugs to these patients and noted if there was any relation between the magnitude of hemodynamic variability and drug responsiveness.

Methods

Subjects: The study includes 12 consecutive patients (8 women, 4 men) referred to the University of Illinois and University of Michigan Hospitals over a 1-year period for evaluation of PPH. They were aged 23 to 60 years old (mean 43 ± 13). Each underwent an extensive work-up to determine the cause of the pulmonary hypertension, but no cause was found.[7] Each patient was admitted to have hemodynamic testing for evaluation of vasodilator therapy while receiving no vasodilator drugs with the exception of digoxin and diuretic therapy.

Hemodynamic monitoring: A Swan-Ganz catheter was directed into the PA, and a small radial artery cannula was placed for hemodynamic monitoring. Each patient was monitored for at least 6 consecutive hours in an intensive care unit, and values were recorded every hour. Heart rate, systolic, diastolic and mean systemic and PA pressures, pulmonary wedge pressure, and right atrial pressure were recorded. Cardiac output was determined by the thermodilution tech-

nique. Systemic and pulmonary resistances were calculated in Wood units from standard formulas.

In each case the serial hemodynamic measurements were made with the patient supine and at rest. Although not the same person made these measurements in all patients, the same person made all of the measurements for any given patient over the 6-hour monitoring period. All measurements were made during the daytime and evening hours. The reproducibility and reliability of the thermodilution technique were assessed at both institutions, with simultaneous thermodilution and Fick cardiac output determinations made on a different group of subjects. The correlation between these techniques was highly significant ($r = 0.81$, $p < 0.001$ at the University of Illinois; $r = 0.96$, $p < 0.001$ at the University of Michigan).

Drug testing: After the 6-hour baseline period was established, 8 patients were administered hydralazine and 10 were given nifedipine. Hydralazine was administered as a 0.3-mg/kg slow intravenous infusion or a 50-mg oral dose, with measurements made after 30 minutes and 2 hours, respectively. Nifedipine was administered as either a 10- or 20-mg oral dose, and the measurements made after 90 to 120 minutes. A new control state was established before each drug test.

Data management and statistical methods: For each patient the mean level of each of the 7 hemodynamic variables over the 6 time intervals was computed along with the standard deviation and coefficient of variation. These summary statistics were used to characterize the average levels and variability of the hemodynamic values for each person. Mean levels of each of these individual means, standard deviations, and coefficients of variation were computed over the 12 subjects in the study.

The Pearson product-moment correlation coefficient was used to evaluate the following associations; the variability in PA pressure with cardiac output, the mean level of each hemodynamic variable with the standard deviation, the change in PA pressure and total pulmonary resistance after drug administration with the previously determined coefficient of variation for those variables, the hourly changes in cardiac output with the mean PA pressure and with the total pulmonary resistance. The significance of the effect of drug administration on the PA pressure and the total pulmonary resistance was evaluated by the t test for paired data.

Under the assumption that within each subject repeated determinations of the hemodynamic variables follow a normal distribution, the probability that 2 determinations in the same individual differ by more than a certain percent can be expressed as a function of the specific percent and the coefficient of variation of the distribution of repeat determinations. For a given coefficient of variation and percent, this probability can be obtained numerically by use of the standard normal distribution. Based on the above rationale, we evaluated this

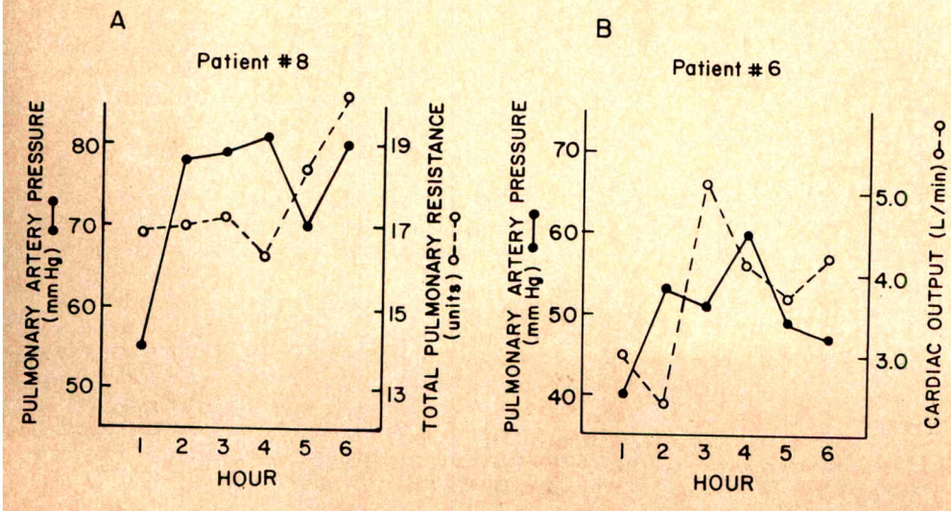

FIGURE 1. The hour-to-hour changes in pulmonary artery (PA) pressure and total pulmonary resistance in patient 8 (**A**) and in PA pressure and cardiac output in patient 6 (**B**). In patient 8, PA pressure increased with essentially no change in pulmonary resistance for the first 4 hours, at which time PA pressure decreased and pulmonary resistance increased dramatically. In the last hour both PA pressure and pulmonary resistance increased together. Patient 6 showed marked variation in PA pressure from hour to hour, without parallel changes in cardiac output. The cardiac output increased substantially between hours 2 and 3 while the PA pressure remained essentially unchanged.

probability using the average coefficient of variation over the 12 subjects as a global estimate of the coefficient of variation.

(Note: In some patients the pulmonary capillary wedge pressure could not always be obtained in consecutive hours. Consequently, total systemic resistance and total pulmonary resistance are being used for statistical analysis in this study. In the cases where left and right ventricular filling pressures were available, we could not find a difference between the amount of variability noted in total systemic resistance and systemic vascular resistance, or total pulmonary resistance and pulmonary vascular resistance.)

Results

Hemodynamic characteristics (Table I): The subjects in the study had advanced PPH as evidenced by the elevated mean PA pressures (64 ± 14 mm Hg) and mean total pulmonary resistance (23 ± 14 units), and reduced cardiac outputs (3.3 ± 1.0 liters/min). The lowest mean PA pressure of any patient in the study was 48 mm Hg, and the lowest total pulmonary resistance was 13 Wood units.

Magnitude of spontaneous variability: Hour-to-hour changes in the hemodynamic values were recorded. The mean levels with the corresponding mean coefficients of variation over the 12 subjects are shown in Table II. In most cases there were unpredictable swings from hour to hour, rather than gradual changes over the 6-hour period. For example, patient 8 had a mean PA pressure rise from 55 to 78 mm Hg, a 42% increase in 1 hour, and patient 6 had a change in cardiac output from 2.4 to 5.1 L/min, a 111% increase in 1 hour, without apparent cause (Fig. 1). Although the changes in pressures seen were not necessarily directly proportional to, or inversely related to the changes in flow in each case, those patients with the greatest variability in their PA pressures also had the most variability in their cardiac outputs ($r = 0.685$, $p = 0.02$) (Fig. 2).

The distribution of the variability in the patients studied was examined to see if it was random. Values of the coefficient of variation of the PA pressures and the pulmonary resistances for each patient are shown in Figure 3. The amount of variability did not appear to be skewed because of patients who were obvious outliers of the group.

Relation between variability and severity of the disease: We examined whether there was an association between the amount of hemodynamic variability and the severity of the disease. There was a significant correlation ($p < 0.01$) between the mean value for total pulmonary resistance and the standard deviation over the 6-hour period ($r = 0.91$), suggesting that patients with higher values for total pulmonary resistance have

* $p < 0.05$.
CO = cardiac outout; PAP = mean pulmonary artery pressure; TPR = total pulmonary resistance.

the most spontaneous hemodynamic variability. This was true for the total systemic resistance (r = 0.78) as well, but not for any of the other measured variables.

Relation between pulmonary blood flow and the corresponding pulmonary artery and pulmonary resistance: The association between the hourly determinations of pulmonary blood flow (cardiac output) and the corresponding mean PA pressure and total pulmonary resistance was analyzed (Table III). A positive linear relation between cardiac output and PA pressure was found in only 1 patient. However, a linear relation was noted between increasing cardiac output and a decreasing pulmonary resistance in 7 of the 12 patients studied. In no patient was an association found between an increasing cardiac output and an increasing pulmonary resistance. Nonlinear relations were not tested.

Spontaneous variation and drug responsiveness: The acute effect of vasodilator administration in the patients studied after the 6 hours of baseline measurements were obtained and analyzed. Hydralazine resulted in an 8% increase in the mean PA pressure and a 16% reduction in pulmonary resistance in the 8 patients tested. Neither of these changes was statistically significant. Nifedipine resulted in 7% reduction in PA pressure and a 25% reduction in pulmonary resistance. Both of these changes were significant (Table IV). There was no correlation between the change in pulmonary resistance or mean PA pressure from administration of either nifedipine or hydralazine and the amount of variation noted to occur spontaneously in these patients.

Magnitude of change required to be attributed to drugs effect: The percentage change in any specific hemodynamic variable that would have to be observed in order for it to be attributed to a drug effect with reasonable confidence, in light of the spontaneous variability that was noted, was derived. A table was constructed that illustrates the percentage change required, based on a 95% confidence level, and the coefficient of variation as determined from this group of patients (Table II). A reduction in mean PA pressure of 22% based on 1 control and 1 postdrug determination, or a reduction in total pulmonary resistance of 36% is required in order to be confident that a vasodilator drug was clearly effective in a single patient. When drugs are evaluated in groups of patients, however, significant drug effects can be determined from parametric testing, as it is assumed that the effect of variability within the group will cancel itself out. Thus, although individual patients tested with nifedipine had changes in PA pressure of less than 22%, the drug had a significant effect on the group as determined by the Student *t* test.

Discussion

The occurrence of spontaneous changes in pulmonary resistance in patients with PPH have been described.[6] A previous study of captopril therapy in PPH showed how the presence of spontaneous hemodynamic variability made the assessment of drug effects difficult.[8] Spontaneous variability is a feature of biologic systems and pathologic manifestations of disease,[9–11] and its quantification is critical in the assessment of drug therapies.[8,12]

This study confirms that hour-to-hour changes in systemic and PA pressure and cardiac output often occur in patients with PPH. This variability may be of similar magnitude in both the systemic and pulmonary circulations, and may be large in some cases. One might question whether the variation observed was due to technical laxity by the personnel making the measurements, but if it were, it should have then been approximately the same from patient to patient. Patients who had the greatest amount of change in their PA pressures also had the greatest change in cardiac output, which is consistent with biologic behavior. Samet and Bernstein[13] suggested that a large amount of variability in pulmonary resistance is indicative of active and reversible vasoconstriction, and is a feature of less advanced disease. However, the amount of variability correlated with the level of total pulmonary resistance, which suggests that variability is a feature of advanced PPH.

We studied the relation between the changes in pulmonary blood flow and the corresponding changes in PA pressure and pulmonary resistance to see if we could determine the mechanisms of variability. In 1 patient the PA pressure increased with the cardiac output, whereas the pulmonary resistance did not, a response characteristic of normal subjects. In 7 patients the pulmonary resistance fell as pulmonary blood flow increased, with the changes in PA pressure independent of the pulmonary blood flow. This would suggest that changes in the cross-sectional area of the pulmonary vascular bed were occurring. Whether this was a result of changing distensibility in the resistance vessels or of vessel recruitment is not known. However, only linear relations between flow and pressure, and flow and resistance were studied and the range of changes in flow was narrow.

TABLE IV Relation Between Vasodilator Drug Testing and Spontaneous Variability

C = control value before drug administration; CV = coefficient of variation for the 6-hour baseline determination; NS = not significant; PA = pulmonary artery; Rx = value after drug administration; SD = standard deviation.

It has also been suggested that the presence of spontaneous variability in pulmonary vascular resistance predict success with vasodilators in treating patients with pulmonary hypertension.[6,14] We could not correlate the amount of variability to drug responsiveness with nifedipine or hydralazine. Neither were the patients with the greatest reduction in pulmonary resistance from the drugs the same ones that appeared to have the most spontaneous change in pulmonary vascular tone. A modest but significant reduction in PA pressure (5 mm Hg) and pulmonary resistance (5 units) occurred with nifedipine, but not with hydralazine.

Because the values were measured every hour, the possibility exists that a drug response measured at an interval of less than 60 minutes may be less influenced by spontaneous variability, or that variability may have a greater influence in the assessment of chronic therapy made over weeks or months. Although these patients were randomly referred to us for study, it is also possible that variability may not be as evident in other patients with pulmonary hypertension, particularly from other causes.

When one reviews previous studies evaluating vasodilator drugs in PPH, one is impressed by the marked lack of uniform criteria that have been used in deciding what magnitude of change determines a beneficial drug response. Based on the patients in this study, we constructed a table that indicates the amount of change required in order to achieve 95% confidence that a hemodynamic effect was drug-related. In an individual patient there must be a relatively large change (e.g., 22% in mean PA pressure and 36% in pulmonary resistance) in order for it to be attributed (with 95% confidence) to a drug effect rather than spontaneous variability (Table II). This must be considered before one makes conclusions about drug effects in individual patients with PPH.

Acute Effects of Alcohol on Left Ventricular Function in Healthy Subjects at Rest and During Upright Exercise

HENNING KELBAEK, MD, THOMAS GJØRUP, MD, INGELISE BRYNJOLF, MD, NIELS JUEL CHRISTENSEN, MD, and JOHN GODTFREDSEN, MD,
With the technical assistance of BIRGIT VESTERGAARD

Six healthy men, aged 23 to 30 years, were studied by radionuclide angiocardiography at rest and at 2 submaximal exercise levels in the upright position during increasing alcohol intoxication. At light intoxication (serum ethanol 23 mmol/liter), the median value of left ventricular (LV) ejection fraction (EF) at rest decreased by 5%. At heavy intoxication (serum ethanol 45 mmol/liter), the median LVEF decreased at rest by 11% and during 75% submaximal exercise by 6%, heart rate at rest increased (median 81 vs 62 beats/min), and systolic blood pressure decreased during 50% submaximal exercise (median 145 vs 163 mm Hg). No significant changes of plasma epinephrine concentrations were recorded, whereas plasma norepinephrine concentrations were increased by 24% at rest during light intoxication and by 30 to 38% during heavy intoxication. No changes of LVEF and plasma catecholamine levels were recorded after ingestion of isovolumic, isocaloric drinks as compared with values obtained before intake. Thus, influences of ingestion per se and repeated investigations of LV function were excluded. These findings suggest that in healthy subjects alcohol intoxication causes a dose-dependent impairment of cardiac contractility. Compensatory mechanisms may account for a reduced influence during exercise.

(Am J Cardiol 1985:55:164–167)

There is evidence that ethanol has both acute and chronic toxic effects on cardiac function, and that changes in cardiac metabolism and hemodynamic alterations are caused by alcohol exposure.[1–3] Although the prevailing view has been that intoxication causes depression of myocardial contractility, studies of acute hemodynamic effects of ethanol in normal subjects have yielded conflicting results,[4–11] probably as a result of different study designs and use of clinical parameters of varying validity as to cardiac function.

Multiple gated cardiac blood pool imaging performed by radionuclide angiocardiography is valuable in the detection of ventricular dysfunction.[12] In addition, the alteration of left ventricular (LV) ejection fraction (EF) during exercise is a sensitive test for detecting latent heart failure.[13] The present study evaluates changes of LVEF at rest and during submaximal exercise in healthy subjects at increasing levels of alcohol intoxication. Plasma catecholamine levels were measured to clarify the significance of the autonomic nervous system masking intrinsic myocardial depression by ethanol.[9]

Methods

Subjects: Six healthy, nonsmoking men, aged 23 to 30 years (median 25) (medical students and physicans), with a daily alcohol consumption of less than 25 g (0.9 oz), entered the study. The median weight was 70 kg (range 60 to 85). The study protocol was approved by the local scientific ethical committee, and each subject gave informed consent.

Procedure: Each subject was studied twice, with an interval of at least 1 week. The subjects were familiar with the investigation schedule when they arrived in the laboratory after at least 6 hours of fasting. Investigations were performed before and during light and heavy alcohol intoxication in the upright position at rest and during steady-state submaximal bicycle exercise corresponding to 50 and 75% of the maximal work capacity as assessed by Åstrand.[14] Data recorded were heart rate (HR), auscultatory blood pressure (BP), precordial electrocardiographic leads, and radionuclide angiocardiography. Venous blood samples were drawn for determination of serum ethanol and plasma catecholamine levels. After initial baseline measurements at rest and during exercise, the

subjects rested for 10 minutes. During the following 20-minute period 0.9 g of ethanol per kilogram body weight was administered in the form of 80-proof whiskey with an equal volume of chilled water. The subjects were thereafter allowed to rest for 30 minutes before data were acquired at rest and during exercise. After a rest period of 10 minutes, an additional amount of whiskey and water corresponding to 0.9 g of ethanol per kilogram was administered and data acquisition was repeated; serum ethanol levels were recorded 30 min after termination of the last exercise performance.

The control study was performed in each subject on another day. The entire investigation program as outlined above was carried out with the exception that ethanol was replaced by an isocaloric, isovolumic solution of a nonalcoholic drink.

Radionuclide angiocardiography: Radionuclide angiocardiography was performed after in vitro labeling of autologous red blood cells with approximately 30 mCi of technetium-99m pertechnetate. Data were collected by aid of an image magnifier with a gamma scintillation camera (PHO, ZLC, Siemens). LVEF was determined in the left anterior oblique projection with a caudal tilt of 5 to 10°, allowing an optimal outlining of the left ventricle. Multiple electrocardiographic-gated equilibrium blood scintigrams were achieved by division of each cardiac cycle into 16 frames. Activity was compiled over 800 to 1,000 beats. Data were acquired in 64 × 64 frame format, and regions of interest were delineated in 128 × 128 frame format of end-diastole and end-systole with a light pen from the isocount contour. Background was defined as an area just inferior and lateral to the apex of the heart. LVEF was calculated as [(end-diastolic counts − end-systolic counts)/end-diastolic counts], with all counts corrected for background activity. End-diastolic and end-systolic areas were determined by counting the number of pixels comprising the area delineated by the light pen.

Plasma catecholamine levels: Plasma epinephrine and plasma norepinephrine concentrations were determined by isotope derivative assay.[15]

Serum ethanol levels: Serum ethanol concentrations were determined by the gas chromatographic method.

Statistical analysis: All data acquired during ethanol intoxication were compared with the appropriate values obtained before alcohol intake. Similarly, data acquired after intake of isocaloric drinks were compared with the values before ingestion.

Statistical analyses were performed by means of the Wilcoxon rank-sum test for paired data. A p value <0.05 was regarded as the level of significance.

Results

Median serum ethanol concentrations at light and heavy intoxication of the subjects were 23 mmol/liter (106 mg/100 ml) and 45 mmol/liter (207 mg/100 ml), respectively (Fig. 1). All data acquired during ethanol intoxication were compared with the values obtained before alcohol intake. At light intoxication, no significant changes in HR or BP were recorded. At heavy intoxication HR at rest was increased (by 81 vs 62 beats/min $p < 0.05$), while systolic BP during 50% submaximal exercise was decreased (145 vs 163 mm Hg, $p < 0.05$) (Table I). A decrease in LVEF at rest was recorded at light intoxication (median 5%), while at heavy intoxication a decrease in LVEF was recorded both at rest (median 11%) and during 75% submaximal exercise (median 6%) (Table II) ($p < 0.05$).

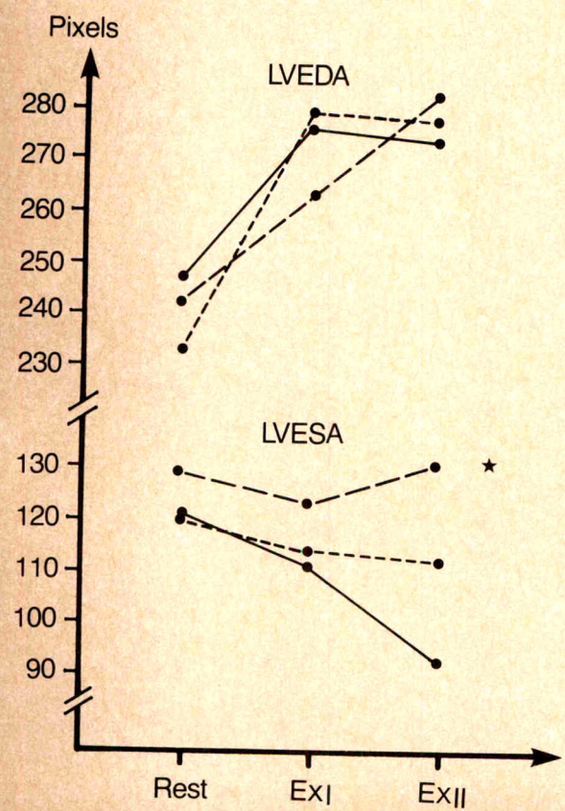

FIGURE 2. Left ventricular end-diastolic areas (LVEDA) and end-systolic areas (LVESA) at rest and during 50% (Ex_I) and 75% (Ex_{II}) submaximal exercise before alcohol intake (●——●), at light (●- - -●), and at heavy (●– — –●) intoxication. * $p < 0.05$ compared with before alcohol intake.

No significant alterations of end-diastolic areas due to ethanol intoxication were recorded (Fig. 2). End-systolic volume tended to increase, but only at heavy intoxication during 75% submaximal exercise did the end-systolic dilation reach significance (median change of LV end-systolic area 141% of the value before intoxication, $p < 0.05$) (Fig. 2).

No significant changes due to ingestion of isovolumic, isocaloric drinks were recorded in any of the investigation variables.

A median increase of 24% ($p < 0.05$) was recorded in plasma norepinephrine concentration at rest during light alcohol intoxication. At heavy intoxication an increase was recorded at rest (median 38%) as well as during 50% and 75% submaximal exercise (median 35% and 30%, respectively, all $p < 0.05$). No significant changes were recorded in plasma epinephrine concentration due to alcohol intoxication (Table III).

Discussion

The results of the present study suggest that alcohol intake causes an acute dose-dependent reduction of LVEF at rest. Similar findings have been reported in experimental[16–19] and clinical[6,7,20] studies. However, it has not been demonstrated previously that a more pronounced adverse effect of ethanol on cardiac performance is recorded at rest than during exercise. This finding indicates that during exercise, compensatory mechanisms are activated to counterbalance the LVEF-reducing effect of ethanol. In normal subjects, an increase of end-diastolic volume with a concomitant decrease of end-systolic volume is recorded during upright exercise.[21] The results of the present control study are in accordance with this concept. During ethanol intoxication, however, LV end-systolic volume as in-

Abbreviations as in Table II.

dicated by pixel area tended to increase, while a reduction of the end-systolic volume during exercise failed to appear (Fig. 2), suggesting that ethanol causes a reduction in cardiac contractility. At heavy intoxication, systolic BP was maintained when LVEF was decreased, indicating an inverse correlation between these variables. Alcohol may have effects on BP during exercise independent of its effects on cardiac contractility. Despite a tendency of LV end-diastolic volume at rest to decrease (Fig. 2), no significant alcohol-induced changes of end-diastolic areas were recorded.

Kupari et al[10] reported echocardiographic findings indicating augmented LV function during the early stage of alcohol intoxication. Changes of LVEF and end-systolic volume recorded in the supine position were small and short-lived, however, and the major reason for the increase in cardiac output was an increase of heart rate. These findings are in accordance with other controlled studies demonstrating no alterations or even slight improvements of LV performance during alcohol intoxication.[4,5,22] In those studies, however, LV stroke volume was taken as an index of LV performance and LVEF was not determined.

In a study by Child et al,[9] no changes of LV function as assessed by systolic time intervals and echocardiography could be demonstrated at a mean blood ethanol level of 110 mg/100 ml (23.9 mmol/liter) in healthy subjects. However, ethanol plus autonomic blockade produced with intravenous propranolol and atropine revealed a decrease in mean velocity of circumferential fiber shortening and an increase in preejection period–LV ejection time ratio. Their suggestion that the ethanol-induced negative inotropic effect is masked by sympathetic nervous system discharge was supported by the present findings, since the reduction of LVEF was accompanied by an increase of plasma norepinephrine.

From the present study we conclude that in healthy subjects; (1) ethanol produces a decrease in cardiac contractility, resulting in a reduced LVEF; (2) the LVEF reduction is dose-dependent; and (3) the changes are most pronounced at rest. Whether the increase in the plasma norepinephrine level is compensatory or a direct ethanol effect on sympathetic nerve endings remains unsettled, as does the inotropic role of catecholamine levels during alcohol intoxication.

Diastolic Time During Recovery from Upright Exercise in Persons Without Heart Disease

TETSURO SUGIURA, MD, TOSHIJI IWASAKA, MD, YOSHINORI L. DOI, MD, BRUCE G. HAFFTY, MD, MITSUO INADA, MD, and DAVID H. SPODICK, MD, DSc

To assess the relation between heart rate and diastolic time (cardiac cycle minus electromechanical systole) during the recovery period from upright exercise, 12 normal volunteers were studied immediately after and 2 and 5 minutes after exercise in the upright position. Although heart rate was significantly lower at 5 minutes compared with 2 minutes after exercise (106 vs 116 beats/min), there was significant shortening of diastolic time (from 251 to 230 ms) and total diastole per minute (from 28,634 to 24,220 ms/min). The explanation of this phenomenon appears to be disproportionate lengthening of diastolic time at 2 minutes after exercise, which must represent physiologic response due to increased left ventricular filling as well as continuing adrenergic effects, which would be diminished at 5 minutes. This lengthening of diastolic time also would maintain decreased subendocardial blood flow caused by increased end-diastolic volume. (Am J Cardiol 1984;54:168–170)

Diastolic time (cardiac cycle minus electromechanical systole) is well known to have a nonlinear relation with heart rate (HR); it increases with decreasing HR. This relation has been determined with various medications,[1] but its consistency during the recovery period from exercise has not been elucidated. This study examines the HR-diastolic time (DT) relation during the recovery period after exercise.

Methods

Subjects: We studied 12 normal volunteers, aged 24 to 49 years, who fulfilled the following criteria: (1) normal medical history and no abnormalities found on physical examination, chest x-ray film and electrocardiogram, and (2) achieving age-predicted submaximal HR with negative electrocardiographic responses.

Recordings: Subjects were studied in the postabsorptive state. Data for systolic time intervals were recorded from the ear densitograph pulse derivative and the electrocardiogram.[2–5] The ear densitograph pulse derivative, because of the demonstrated stability of the pulse transmission time, is a reliable, reproducible pulse measurement for determining all the systolic time intervals in various conditions.[3–5]

Ear densitograms were obtained with a Hewlett Packard 780-10 photoelectric earpiece, modified and filtered through a Hewlett Packard 7712 recording system, as previously reported.[6] Recordings were made on a Cambridge 3044B 3-channel stress test system at a paper speed of 100 mm/s.

Procedure: Subjects exercised on a Quinton Type 18-54 treadmill without interruption to their submaximal HR. Recordings were made immediately after and 2 minutes and 5 minutes after exercise and recovery with the patient in the sitting position. With each of these recordings cuff blood pressure was measured.

Measurements: Methods for measuring HR, preejection period (PEP) and left ventricular ejection time (LVET) are described elsewhere.[3,5] DT was calculated as cardiac cycle (RR) minus electromechanical systole (QS_2): QS_2 = PEP + LVET. Measurements of HR and systolic time intervals were aided by a digitizing technique using a Summagraphics digitizer coupled to a DEC-20 computer, and were calculated from means of 5 consecutive beats for each of the recordings. Total diastole per minute (DT × HR) was also evaluated.

Statistical analysis: The *t* test for paired sample was used to compare each postexercise value. The other systolic time intervals, PEP, LVET and their ratio were also calculated.

Results

Results are summarized in Figure 1 and Table I. **Responses immediately after and 2 minutes after exercise:** HR and double product (systolic blood pressure × HR) decreased significantly during this period ($p < 0.001$ and $p < 0.001$, respectively), while QS_2 lengthened significantly ($p < 0.001$). There was significant lengthening of DT and total diastole per minute during this period ($p < 0.001$).

Responses 2 and 5 minutes after exercise: Despite a significant decrease in HR, there were "paradoxical"

DP = double product; DT = diastolic time; 5 = 5 minutes after exercise; HR = heart rate; I = immediately after exercise; %Δ = percent change from value immediately after exercise; QS_2 = electromechanical systole; SD = standard deviation, SE = standard error of the mean; 2 = 2 minutes after exercise.

shortening of DT and total diastole per minute (Fig. 1, Table I). Double product decreased and QS_2 increased significantly during this period ($p < 0.001$ and $p < 0.001$, respectively).

PEP, LVET and PEP/LVET progressively increased during the recovery period (Table II).

TABLE II Changes in Systolic Time Intervals (ms) After Exercise

	Immediate	2 min	5 min
PEP	54 ± 7	71 ± 11	98 ± 10
LVET	172 ± 19	202 ± 27	238 ± 22
PEP/LVET	31 ± 5	36 ± 5	41 ± 5

Values are mean ± standard deviation.
LVET = left ventricular ejection time; PEP = preejection period.

Discussion

Although HR decreased throughout the recovery from exercise, DT shortened significantly at 5 minutes after exercise, which was opposite to the expected relation. Compared with HR immediately after exercise, a significant decrease in HR (lengthening of RR interval) and lengthening of QS_2 were seen as well as lengthening of DT at 2 minutes after exercise. At 5 minutes after exercise, despite lengthening of the RR interval and QS_2, DT shortened significantly compared to 2 minutes after exercise. An increase in HR (shortening of RR interval) or lengthening of QS_2 will cause shortening of DT. Shortening of DT during 2 minutes to 5 minutes after exercise was accompanied by a decrease in HR and lengthening of QS_2. Possible explanations for the shortening of DT are: (1) DT at 2 minutes after exercise was disproportionately prolonged (QS_2 shortened) and (2) DT at 5 minutes after exercise was disproportionately shortened (QS_2 prolonged) for a given HR. Despite the smaller reduction of HR (29%) at 2 minutes compared with 5 minutes (35%) after exercise, percent lengthening of DT at 2 minutes (76%) was larger than 5 minutes after exercise (61%). In addition, total diastolic time per minute at 2 minutes after was significantly longer than immediate or 5 minutes after exercise. Thus, for this phenomenon, the primary factor appears to be the disproportionate lengthening of DT at 2 minutes after exercise, causing a fundamental change in the HR-DT relation.

An increase in cardiac function associated with increase in end-diastolic diameter or stroke volume during the recovery phase, has been postulated.[7–10] In our patients, reduction in double product (less oxygen demand)[11] and lengthening in QS_2 (less sympathetic stimulation to the heart)[12,13] were seen throughout the recovery period. Therefore, this disproportionate prolongation of DT at 2 minutes after exercise, while related to continuing adrenergic effects on QS_2 (i.e., shortening) must be related to elevated left ventricular filling (faster decrease in HR than venous return) at 2

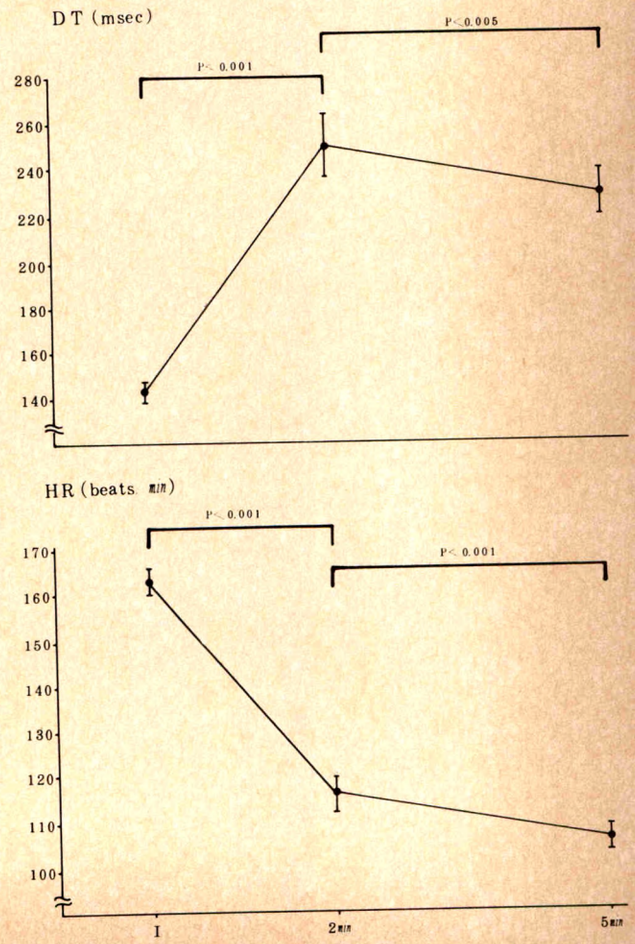

FIGURE 1. Behavior of diastolic time (DT) and heart rate (HR) during early recovery period of treadmill exercise. Values are mean ± standard error of the mean. I = immediately after exercise; 2 min and 5 min = 2 and 5 minutes after exercise.

minutes, diminished adrenergic effects on duration of systole (QS_2) or both. It is also a desirable mechanism to maintain decreased subendocardial coronary blood flow caused by an increase in end-diastolic volume.[9,14]

This direct relation of DT and HR from the second to the fifth minute of the recovery phase after treadmill exercise observed in this study implies that this relation is a physiologic phenomenon, despite the general nonlinear, inverse relation of DT with HR.

The changes (progressive increases) in PEP, LVET and PEP/LVET (Table II) represent the expected postexercise restitution changes.[5,7,15,16]

Radiation Exposure and Protection in Cardiac Catheterization Laboratories

STEPHEN W. MILLER, MD, and FRANK P. CASTRONOVO, Jr., PhD

Cardiac catheterization with angiography can deliver the greatest dose of x-radiation of any diagnostic medical examination. The physicians and technologists in the angiography room receive low-level scattered radiation over a period of months to decades. Although the radiobiology is complex, the physicians who perform cardiac catheterization should be familiar with the potential genetic and somatic effects of radiation and with the methods to reduce or eliminate x-ray exposure. The aim of radiation protection criteria is to reduce the risk of cancer death to less than the fatality risk for other occupations regarded as safe. This report is a review of the literature relating to radiation exposure and protection in cardiac catheterization laboratories. Catheterization personnel have control over the time duration of exposure, placement of technologists, shielding, location of equipment and monitoring of dose received.

(Am J Cardiol 1985;55:171–176)

Cineangiography is used daily for the evaluation of patients with heart disease. Cineangiography and fluoroscopy combined make cardiac catheterization the producer of the largest x-ray dose of any examination in diagnostic radiology.[1,2] The use of x-rays in the catheterization laboratory is generally acceptable because the expected benefits derived from the angiography are considered to outweigh the risks. What are the risks from radiation exposure in the cardiac catheterization laboratory and how can they be reduced?

Sources and Amounts of Radiation Exposure

Numerous studies have documented the radiation exposure to patients and personnel during cardiac catheterization procedures.[3–10] The amount of radiation received varies widely among laboratories and depends on the type of equipment used, the operating techniques and length of the procedure, the shielding of the x-ray beam, and the administrative procedures regarding the placement of personnel. The amount of radiation received from a given medical procedure can be compared with that received annually from natural and artificial sources (Table I).

A nationwide survey by the Bureau of Radiological Health estimated that 65% of the people in the United States were exposed to medical or dental x-rays in 1970.[11] Studies have shown that the largest source of exposure of the population to man-made radiation is medical and dental radiologic procedures.[11,12] The mean dose rates to patients and physicians during cardiac catheterization are listed on Table II. These values are a summary from different types of room installations and procedure times. Most of the patient dose for cardiac procedures is delivered directly by the beam to the thoracic area. Patient-scattered radiation affects mainly the thyroid in adults but also the eye and abdomen in the child. Personnel exposures result from the primary x-ray beam being scattered by tissue in the patient's thorax. The chest, thyroid and eyes receive most of the scattered radiation (Fig. 1).

Genetic and somatic effects of low radiation doses have been the subject of many reviews.[13–16] Genetic effects are those that affect the germ cells and may be transmitted to the progeny. Somatic effects include malignancies, especially leukemia, cataracts, and developmental abnormalities of children exposed in utero.

The incidence of radiation-induced genetic disorders in humans is uncertain, not only because of the lack of acceptable data but also because of the large number of mutations that are already carried by persons. The incidence of human genetic disorders occurring spontaneously is greater by a factor of 100 compared with that which would additionally occur from parental x-ray exposure.[12] Therefore, the frequency of detectable somatic effects greatly exceeds that resulting from genetic effects.

† One hundred rem = 1 Sievert (Sv); 1/100 mrem = 1 mSv.

Cancer induction appears to be the most important somatic effect of low-dose ionizing radiation, defined as less than 100 rem (1 Sievert [Sv]). These cancers may be either benign or malignant and are indistinguishable from those occurring naturally. A radiation dose greater than 100 rem (1 Sv) unequivocally is leukemogenic in adults. However, the induction of cancer by lesser amounts of radiation is detectable only by statistical means and cannot be attributed with certainty to a spontaneous occurrence, radiation or some other cause.[14] Cancer occurrence in radiologists has been analyzed over an 80-year period from 1897 to 1977.[17] For radiologists who entered the profession before 1921, when improved radiation protection measures were introduced nationally, there was an excess of cancer deaths compared with physicians in other specialties. For those who entered the profession after 1935, there has been a deficit of cancer deaths relative to other physicians. Because radiation-induced cancers have a latent period of up to 40 years after exposure, one may not conclude that the risk of radiation-induced cancer has been eliminated by modern protective measures. In the diagnostic range of less than 10 rem (0.1 Sv), there are no scientifically well controlled studies to indicate that the incidence of malignant disease is increased in humans.

Cataract production can result from long-term, low-level x-ray exposure.[18] After a latent period of several years, a reasonably defined threshold of about 250 rem (2.5 Sv) results in diffuse cataracts. Smaller opacities have developed in the lenses of mice subjected to only 50 rem (0.5 Sv).[19]

Personnel Radiation Dose for Cardiac Angiography

The National Council on Radiation Protection has established maximal permissible doses for persons who receive occupational exposure.[20] There are no standards for patients. For personnel working with by-product material (reactor produced), the Nuclear Regulatory Commission has suggested that occupational exposure should be as low as reasonably achievable (ALARA) (Table III). Quarterly exposures in excess of level 1 amounts are reviewed by the radiation safety officer. Level 2 exposures are 3 times those of level 1 and require a written report to the Nuclear Regulatory Commission describing why the high-dose level occurred and steps taken to reduce the dose in the future. At our institution we have extended the ALARA concept to personnel exposure from diagnostic x-rays.

Personnel monitoring of radiation dose is frequently accomplished with a standard film badge. Its proper placement, however, is being debated. One report recommends the badge be worn on the collar of a lead apron, because this part of the body is most likely to receive the greatest proportion of the permissible dose.[21] Other investigators recommend the proper placement of the badge for estimation of whole-body dose to be on the trunk under the apron.[22] Ideally, a second dosimeter could be worn on the collar during fluoroscopic and catheterization procedures, as is the case at our institution. Film badge dosimeters are calibrated to measure dose equivalent in mrem (mSv). Film badge records for

TABLE III Summary of ALARA Guidelines for Limiting Personnel Exposure to Diagnostic Equipment*

Organ	Maximal Permissible Dose (mrem)		ALARA	
	Year	Quarter	10% MPD Level I	30% MPD Level II
Whole body (including gonads, lens of eye, red bone marrow)	5,000	1,250	125	375
Forearms, hands, feet and ankles	75,000	18,750	1,875	5,625
Skin of whole body	30,000	7,500	750	2,250
Pregnant women or employees <18 years of age	500	125	125	375
Neck (thyroid)	15,000	3,750	375	937

* No maximal permissible limits are set for patient exposure.
ALARA = as low as reasonably achievable; MPD = maximal permissible dose.

hospital radionuclide and x-ray personnel show that the mean annual dose for 1975 was 350 mrem (3.5 mSv); 90% of all personnel, including angiographers, had cumulative annual doses of less than 500 mrem (5 mSv).[11] Average exposures for different types of cardiac catheterization procedures are shown in Table IV.[6]

Equipment Considerations

Cineradiographic exposure depends on the radiation dose per frame and the length of the filming time. Published x-ray exposures range from 10 to 120 μR/frame.[23] At the usual rate of 60 frames/s and 25 μR/frame, the adult skin exposure rate ranges from 45 to 90 R/min (0.45 to 0.9 Sv/min). A lesser radiation dose per frame would produce a poor-quality image due to statistical fluctuations in the spacial distribution of x-ray photons on the film (quantum mottle). The report of the Inter-Society Commission for Heart Disease Resources[24] has recommended 30 to 40 μR/frame for a 15- to 17-cm field-size image intensifier as a balance between picture quality and minimal radiation exposure to the patient. Included in this report[24] are recommendations for beam limitation devices, reduction of scatter by additional shielding around the table, and other shields to protect personnel not required in the room for performance of the procedure. A cardiologist should be aware of the output of the x-ray equipment being used. For example, the microroentgen per frame measurements should be made annually or each time a major component of the x-ray unit is changed. A comprehensive quality control program should be implemented to optimize the performance of other components in the cineradiographic system, such as x-ray generators, image intensifiers, optical systems and film processors.[23]

Protective Measures: Time, Distance and Shielding

Specific radiation protection measures that are applicable to all cardiac catheterization laboratories are difficult to prescribe. Certain general radiation protection principles can be adapted for each laboratory. Three variables are the duration of the radiation, shielding and the distance of personnel from the x-ray source.

TABLE IV Average Calculated Time and Exposure for Eye and Thyroid During Cardiac Catheterization*

	Time (min)	Exposure mrem (mSv)	
		Eye	Thyroid
Right heart catheterization	15.3	4.9 (0.049)	4.2 (0.042)
Left ventriculography	9.4	3.3 (0.033)	2.8 (0.028)
Right coronary angiography	10.5	9.1 (0.091)	7.7 (0.077)
Left coronary angiography	7.0	6.5 (0.065)	6.2 (0.062)
Total procedure	50.4	31.1 (0.311)	27.6 (0.276)

* Modified from Rueter.[6]

About half of the cardiac catheterization exposure comes during fluoroscopy and the remainder during cineangiography.[4,6,10] The fluoroscopy time can be considerably reduced by using short bursts on the fluoroscope rather than a prolonged, continuous exposure.

The limiting occupational exposure to physicians performing cardiac catheterization is eye exposure. Rueter[6] estimated that the lens of the eye of the cardiologist receives an average exposure of 20 mR (0.2 mSv) during coronary angiography, left ventriculography and related fluoroscopy.[6] Figures 1 and 2 show the intensity and distribution of scattered radiation around the angiography table. Based on a recommended maximal dose of 100 mrem (1 mSv)/week to the lens of the eye for occupational workers, a cardiologist should be limited to approximately 5 procedures per week. Rotation of nurses and technicians into nonradiologic areas increases the time interval between exposures and may lessen the likelihood of an individual receiving an excessive exposure.

Newer angiographic equipment with U-arms or C-arms allows compound angled oblique projections. Because the x-ray beam must penetrate an additional thickness of tissue with this equipment, the 40° cranial view may have 2 to 3 times the entrance dose of a stan-

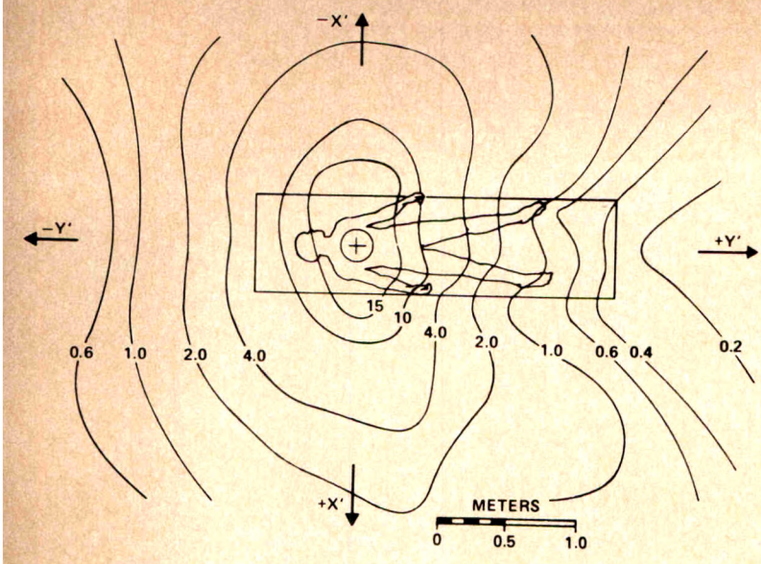

FIGURE 2. Pattern in the horizontal plane of exposure values (milliroentgen/hour) during cardiac catheterization. Typical values of 96 kVp, 10 × 10 cm field and 1.95 R/min tabletop exposure rates were used. (Reprinted by permission of the American Heart Association and from Rueter.[6])

dard frontal projection.[25] The cranial position of the x-ray tube during angulation can result in more scattered radiation to medical personnel (Fig. 3).

The concern about x-ray exposure during pregnancy has been discussed both for the woman as a patient and for the physician performing the catheterization. The American College of Obstetricians and Gynecologists in their guidelines for diagnostic x-ray examinations have suggested that attempts to schedule studies of women of reproductive age in relation to menstrual cycle are of little value, and there is no measurable advantage for scheduling examinations at any particular time during the normal menstrual cycle.[26] An estimation of a conceptus dose in pregnant woman radiologists has suggested that a woman cardiologist would receive less than 1 mrem (0.01 mSv) of gonadal dose per examination and therefore could perform 5 catheterizations per day and still receive less than the maximal permissible conceptus dose of 500 mrem (5 mSv)/gestation.[27]

Because radiation decreases as the square of the distance from the source, all personnel who are not needed in the room should be located elsewhere. For instance, the electrophysiologic data collection can be performed from a remote location rather than beside the fluoroscopy table. Nurses and technicians who remain in the room should be as far away as practical from the x-ray tube. Although coronary angiography is traditionally performed by using a hand-injection technique, all angiographic procedures can be accomplished with a power injector, thereby allowing all personnel to leave the room during the cineangiography.

Lead shielding is the third method to reduce personnel exposure. Collimation of the x-ray beam reduces secondary scatter to the patient and physician and also improves image quality. Movable shields or drapes are available for most of the current angiographic units. Side drapes between the patient and operator reduce scatter from the patient that would otherwise be received by the cardiologist. Specially designed shields have been developed for C-arm imaging systems, which are used for compound hemiaxial projections.[28] Because the thyroid and eyes receive most of the scattered radiation, thyroid shields and leaded eyeglasses may be used by a full-time angiographer.[29] These protective devices are recommended by the ALARA guidelines for those who perform many studies. Multilayered lead aprons with the equivalent of 0.5 mm of lead are available in multiple configurations. The selection of an apron will depend on the task of the laboratory personnel; technologists with their back to the patient should wear a full wraparound apron. If this type of apron is too heavy, a 2-piece apron is available consisting of a jacket and a skirt.

Protection of the patient during cardiac catheterization consists mainly of shielding the gonadal area. Once the catheters have been introduced from a femoral arterial site, both male and female patients should have the reproductive organ dose decreased by placing a lead apron beneath the pelvis for an under table tube location. Gonadal shielding is of particular importance in pediatric patients because the primary beam centered on the thorax is much closer to the gonads than in the adult.

Conclusion

There is no dose of radiation that can be considered safe or harmless. Because diagnostic x-rays are the greatest single source of man-made radiation, the physician must assess judiciously the benefits and risks of medical x-rays. Exposure of patients with almost certain pathologic findings to x-ray radiation is justified to produce a diagnostic image if danger of the present disease outweighs the small probability of future hazard from radiation. Examples are the patient who is to undergo coronary artery surgery or the cyanotic infant who needs an immediate and accurate anatomic diagnosis. However, in a longer time frame, the physician, nurses and technologists working in the cardiac catheterization laboratory are subjected to a very low dose of scattered radiation, which is absorbed over a period of months to years to decades. Personnel dose-reduction techniques

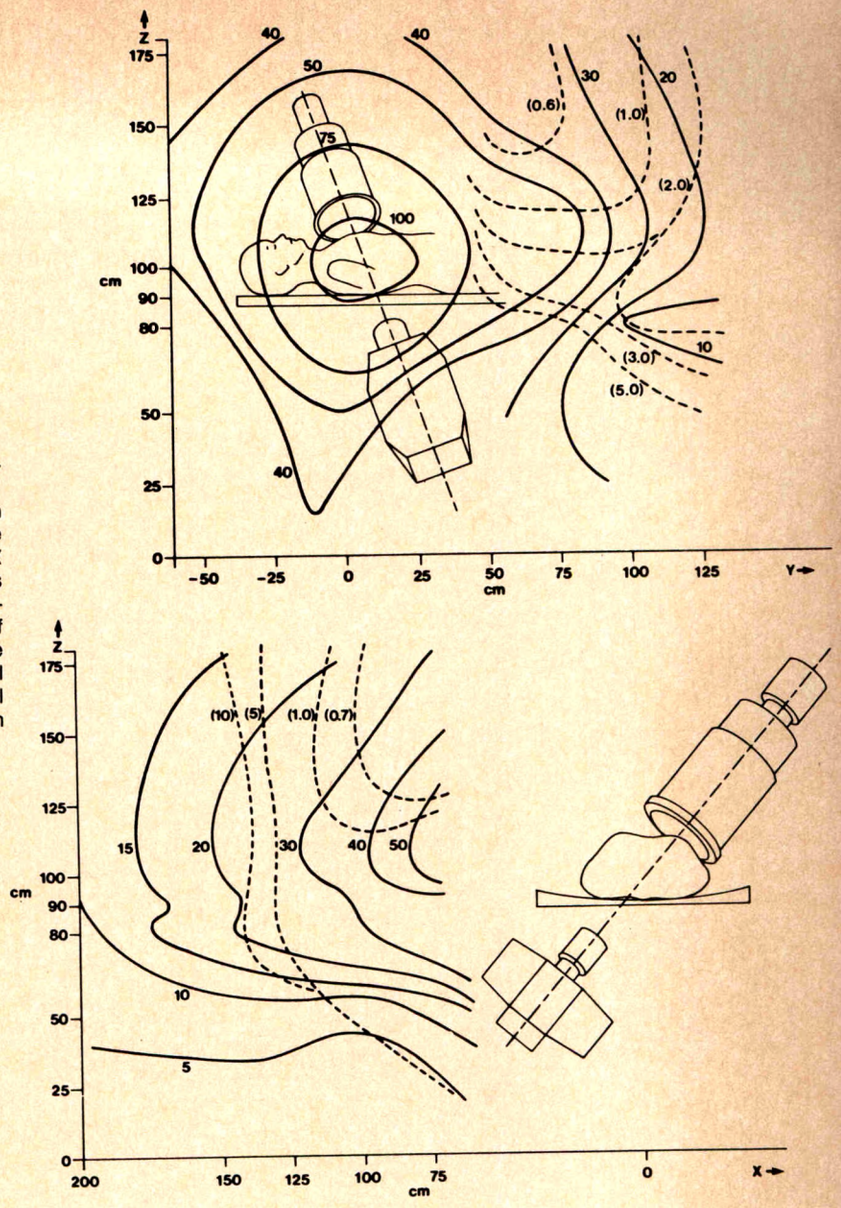

FIGURE 3. Isoexposure curves expressed in milliroentgen/hour for the 50° left anterior oblique 15° cranial angulation in (top) the longitudinal plane with the operator at 75 cm on the Y axis, and (bottom) the horizontal plane with the operator at 75 cm on the X axis. **Solid lines** indicate radiation exposure levels without the protection of the shield; **dashed lines** indicate values with the shield. The vertical center of shield is at 75 cm in both the X and Y planes with the operator behind the shield. Z represents the vertical plane, Y the longitudinal plane, and X the horizontal plane. should consider the time of the study, placement of personnel, available shielding, location of equipment, adequate monitoring (radiation badge) and a complete quality control program. The aim of an adequate radiation protection program is to reduce the genetic and somatic risks to below the risk for other occupations regarded as safe.[30,31] Risk estimates in the low-dose region involve a great deal of uncertainty and are based in part on incomplete data. The magnitude of the risk to the persons exposed must be kept in perspective if they are to derive a benefit from the medical use of ionizing radiation.

Accuracy of Left Ventricular Ejection Fraction Using the Nuclear Stethoscope in Left Ventricular Aneurysm

DAVID M. McCARTHY, MD, and P. TODD MAKLER, Jr., MD

Although the nuclear stethoscope, a nonimaging probe, accurately determines left ventricular (LV) ejection fraction (EF), its reliability in patients with LV aneurysm has not been established. Accordingly, LVEF was determined using the nuclear stethoscope and compared with that determined by equilibrium gated blood pool scanning in 29 patients, 1 studied on 2 separate occasions, for a total of 30 patient studies. Patient studies were separated into 2 groups. Patients in group I (n = 20) had no gated blood pool evidence for aneurysm, and those in group II (n = 10) had discrete focal akinesia or dyskinesia. Nineteen patients (13 in group I and 6 in group II) had 2 separate nuclear stethoscope acquisitions. In group I, EF determined by gated blood pool scanning (53 ± 4%, mean ± standard error) did not differ from that determined by nuclear stethoscope (51 ± 4%). EF determined using either gated blood pool scanning (32 ± 6%) or nuclear stethoscope (35 ± 5%) was significantly lower in group II than in group I, although nuclear stethoscope and gated blood pool scanning did not differ. Reproducibility was excellent (r = 0.96). Overall, nuclear stethoscope and gated blood pool EFs correlated closely (r = 0.93), and the correlation coefficients were similar in groups I (r = 0.92) and II (r = 0.92). The slopes of the regression curves for group I (0.97) and group II (0.92) were not statistically different. These results confirm the accuracy and reproducibility of LVEF determination by nuclear stethoscope and specifically demonstrate its reliability in patients with LV aneurysm.

(Am J Cardiol 1985;55:177–180)

Nonimaging nuclear probes accurately determine left ventricular (LV) ejection fraction (EF).[1–7] These devices consist of a single-crystal and photomultiplier tube. They are portable and significantly less complex and expensive than standard nuclear medicine camera-computer imaging systems. The counting rate sensitivity also permits measurement of LV function on a beat-to-beat basis.[5,8] This probe has 2 attributes that may limit its usefulness in patients with LV aneurysm: A fixed region-of-interest is used for data acquisition and analysis, and the instrument is positioned "blindly" over the heart. These potentially limiting effects in patients with LV aneurysm have been discussed,[5] and decreased accuracy of EF determination in such patients has been reported.[6] Because global LVEF has important prognostic and therapeutic implications,[9,10] the reliability of such determination in patients with LV asynergy is important. This study evaluates the accuracy of LVEF by a nonimaging probe in patients with and without LV aneurysm.

Methods

Patients: The patient population comprised 29 patients undergoing routine gated blood pool (GBP) scanning for clinical indications. There were 20 men and 9 women, aged 32 to 84 years (mean 55). One patient was studied on 2 separate occasions, for a total of 30 patient studies. The patients were separated into 2 groups based on the results of the GBP scanning. Group I comprised 19 patients (1 studied twice for a total of 20 studies) with no evidence of LV aneurysm. LV wall motion was normal in 14 and hypokinetic in 5. Cardiac diagnoses included coronary artery disease in 4 patients, congestive heart failure in 4, valvular heart disease in 3, hypertensive heart disease in 3, and hypertrophic cardiomyopathy in 1 patient; 4 patients had no heart disease. Group II comprised 10 patients with coronary artery disease (1 with coexisting valvular heart disease and 8 with ventricular tachycardia) who had discrete akinesia or dyskinesia indicative of LV aneurysm.[11] Dyskinesia was present in 5 patients and akinesia in 5. The location of the aneurysm was inferior in 2 patients, inferoapical in 2 and apical in 6. Confirmation of the presence of LV aneurysm was available by 2-dimen-

sional echocardiography (2 patients) or cardiac catheterization (8 patients, 4 of whom also had surgical confirmation).

Study design: Patients were included in the study if the nonimaging probe study could be performed at the time of GBP scanning. Red blood cells were labeled in vivo using 15 mCi of technetium-99m pertechnetate.[12] LVEF was determined in all patients by both a standard GBP camera technique and a nuclear probe. The sequence of studies alternated (i.e., GBP or probe study first). The results of the first EF determination were not made available to the person making the second determination.

Nuclear stethoscope: Probe studies were performed on a commercially available computerized nuclear probe, the Nuclear Stethoscope® (Bios, Inc.), which consists of a 2-inch-diameter × 1½-inch-thick NaI (Tl) crystal with a single-bore 3.5 inch converging collimator which is interfaced to a dedicated microprocessor. This instrument has been described in detail elsewhere.[13] The probe was positioned over the heart using a previously described computer-assisted algorithm.[5] Once the probe was positioned, gated equilibrium studies were initiated in the ventricular function mode for 60 or 120 seconds, depending on the observed count rate. Typical count rates in this study were 1,500 counts/50 ms (i.e., 30,000 counts/s). In 19 patients, 2 separate probe studies were performed with complete repositioning of the instrument between studies. All probe studies were performed by 1 of 2 physician operators who had previous experience with the nuclear stethoscope.

Gamma camera studies: Multigated blood pool imaging was performed on a single-crystal gamma camera (Picker-Dynamo®) interfaced to a dedicated nuclear medicine minicomputer (DEC Gamma-11®). Studies were acquired in the anterior, "best septal" (usually 35 to 45°) left anterior oblique (LAO), and 70° LAO views. R-wave synchronized multigated scans were acquired with 24 frames spanning the cardiac cycle for an average of 250,000 counts/frame. Beats that fell outside a ±10% RR interval window were rejected. LVEF was calculated from the "best septal" LAO view using a variable region-of-interest software program. The calculation was performed by an independent observer who was not aware of the results of nuclear stethoscope studies. Wall motion was assessed in all 3 views for the presence or absence of LV aneurysm (discrete akinesia or dyskinesia).[11]

Statistical analysis: Data are expressed as the mean ± standard error of the mean (SEM). Differences were analyzed using a Student *t* test for paired or unpaired data as appropriate. The EF determinations by gamma camera and nuclear stethoscope were compared using linear regression analysis, as was the reproducibility of nuclear stethoscope determination in the 19 patients undergoing 2 determinations. The slopes of the regression lines for patients with and without aneurysm were compared using the 2-tailed Student *t* test.[14]

Results

Among the 30 determinations in the 29 patients, EFs ranged from 11 to 82%. The mean GBP EF in group I was 53 ± 4%, which was not significantly different from the nuclear stethoscope EF (51 ± 4%) (Fig. 1). In group II, the GBP EF was 32 ± 6%, which was significantly less than that in group I ($p < 0.05$). Again, the nuclear stethoscope EF (35 ± 5%) did not differ significantly from that determined by GBP scanning.

In the entire group, linear regression analysis revealed a close relation ($r = 0.93$) between EF calculated by either nuclear stethoscope or GBP scanning: $EF_{NS} = 0.92\ EF_{GBP} + 0.04$. When the 2 groups were analyzed individually, this close correlation between the 2 techniques remained. In group I (Fig. 2), the EF determinations were closely correlated ($EF_{NS} = 0.97\ EF_{GBP} + 0.01$, SEE = 0.08, $r = 0.92$). In group II (Fig. 3), $EF_{NS} = 0.92\ EF_{GBP} + 0.06$, SEE = 0.07, $r = 0.92$. In the 19 patients who had 2 separate nuclear stethoscope determinations (13 from group I and 6 from group II), reproducibility was excellent (Fig. 4): $y = 0.96x + 0.02$, SEE = 0.05, $r = 0.96$.

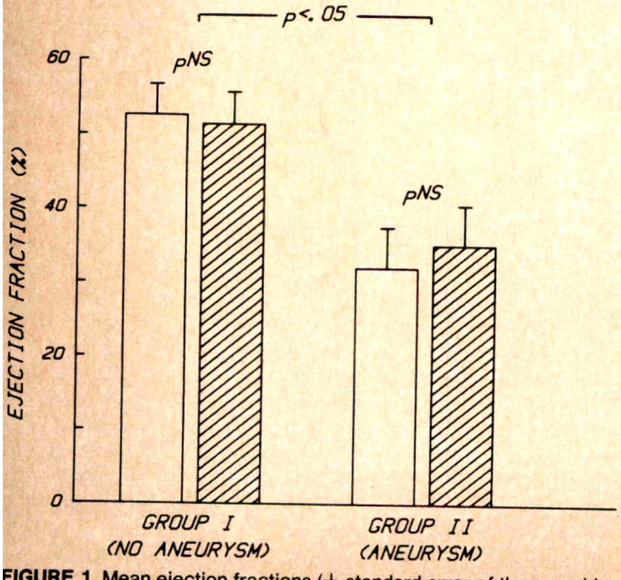

FIGURE 1. Mean ejection fractions (± standard error of the mean) by gated blood pool scanning (**open bars**) and nuclear stethoscope (**hatched bars**). NS = not significant.

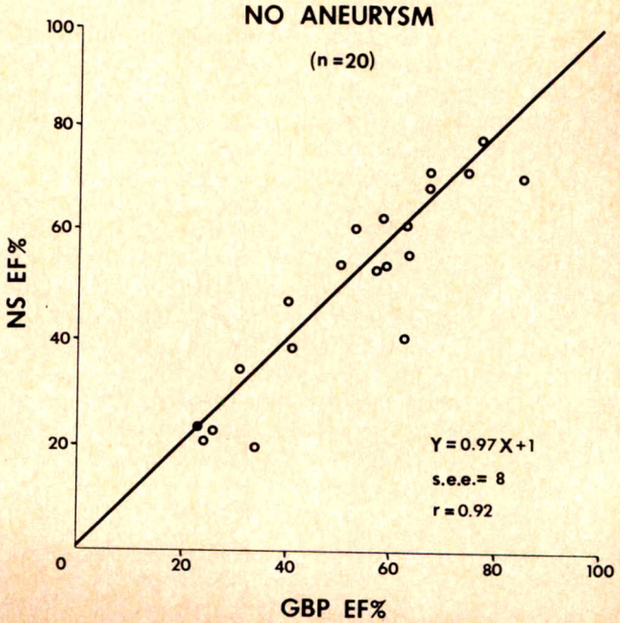

FIGURE 2. Comparison of ejection fraction (EF %) by nuclear stethoscope (NS) and gated blood pool (GBP) scanning in group I.

Discussion

The results of this study confirm the accuracy of LVEF determination using the nuclear stethoscope, and in particular demonstrate its accuracy in patients with LV aneurysm. Previous studies using the nuclear stethoscope[4–7] or other nonimaging probes[1–3] have also demonstrated the accuracy of LVEF determination by this method. Wagner et al[4] evaluated 2 versions of the nuclear stethoscope. A prototype model yielded a good correlation with camera-computer EF determination (r = 0.81), and improved with a later version similar to the present instrument in which positioning is facilitated by a microprocessor-based algorithm (r = 0.92). These studies were conducted on a series of patients, some of whom had coronary artery disease, but without comment on the presence or absence of regional wall motion abnormalities. Other investigators, using either the nuclear stethoscope[5–7] or other nonimaging probe devices[1–3] have reported correlation coefficients vs standard (radionuclide or catheterization) techniques ranging between 0.85 and 0.92.

The nuclear stethoscope is a nonimaging radionuclide detector that differs from standard camera-computer studies in several respects, at least 2 of which may limit its accuracy in patients with LV aneurysm. First, the device is positioned "blindly" over the left ventricle. Positioning has been facilitated by the use of a microprocessor-based algorithm which monitors relative stroke count changes on a beat-to-beat basis as the probe is moved in position over the chest.[5,13] Although this positioning algorithm has improved the accuracy of LVEF determination,[4] it could lead to an overestimation of true EF in patients with aneurysm if the probe is positioned over a normally contracting region and excludes the area of akinesia or dyskinesia. Also, since the probe uses a fixed region of interest to assess changes in LV volume, an enlarged left ventricle may be incompletely viewed by the device, resulting in an underestimation of the true EF.

These and other technical limitations of nuclear probes have been discussed,[3,5] and the results of EF determination in patients with dyssynergy have been inconsistent. Berger et al[5] studied 71 randomly selected patients, including 23 with discrete regional wall motion abnormalities. Their overall correlation with radionuclide EF was good (r = 0.92), and they reported that the correlation between probe and camera EFs was comparable in patients with and without regional wall motion abnormalities. However, Strashun et al[6] compared the nuclear stethoscope EF in 42 patients with normal wall motion and in 26 patients with regional asynergy, and found a better EF correlation in the group with uniform wall motion (r = 0.86) than in the group with regional abnormalities (r = 0.68). In the latter group, there was a significant overestimation of EF by the nuclear stethoscope. In the study of Høilund-Carlsen et al,[7] the EF determined by nuclear stethoscope in 12 patients with wall motion abnormalities was significantly higher than that measured by gamma camera, while the EFs in patients with normal contraction patterns were slightly (but insignificantly) less than those measured by gamma camera. Correlation coefficients for each subgroup were not reported. Bacharach et al[3] reported a good correlation coefficient (r = 0.90), even though 11 of their 20 patients with coronary artery disease had wall motion abnormalities.

In the present study, patients were grouped according to the presence or absence of LV aneurysm. Although

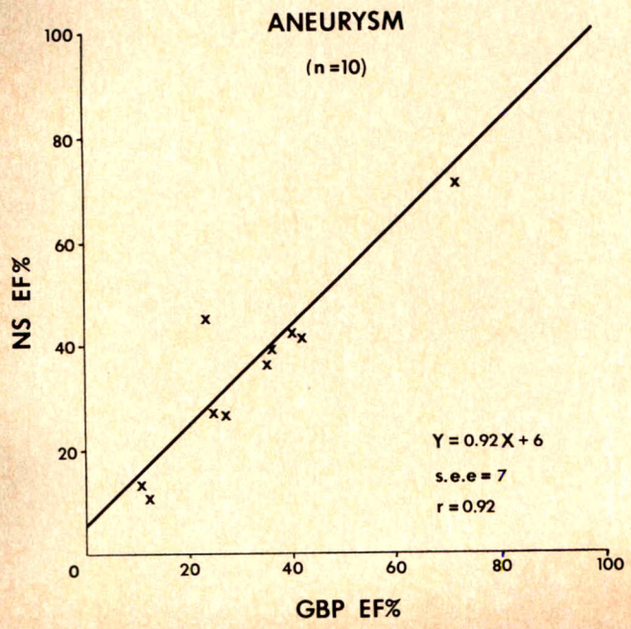

FIGURE 3. Comparison of ejection fraction (EF%) by nuclear stethoscope (NS) and gated blood pool (GBP) scanning in group II.

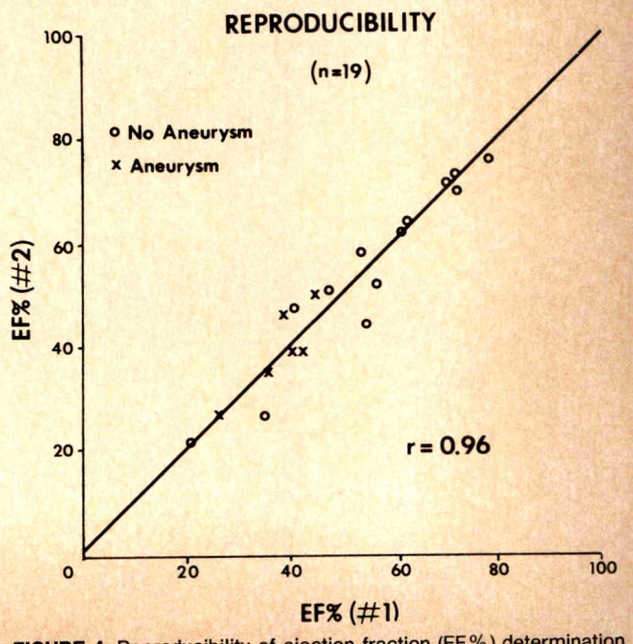

FIGURE 4. Reproducibility of ejection fraction (EF%) determination using the nuclear stethoscope with 2 separate data collections.

the mean LVEF by nuclear stethoscope (35 ± 5%) was slightly higher than that by gamma camera (32 ± 6%) in the patients with aneurysm, this difference was not statistically significant. In addition, the correlation coefficients and standard errors of the estimate of EF determination in the group with aneurysm was similar to that in the group without aneurysm (Fig. 2 and 3). The slope of the regression line in the patients with aneurysm (0.92) was not statistically different from that in the patients without aneurysm (0.97). Reproducibility was excellent for both types of patients (Fig. 4).

Berger et al[5] discussed the theoretical overestimation of true EF in aneurysm patients and stated that it may apply mostly to patients with inferior dyssynergy, rather than the more common anteroapical aneurysms. The differential effects of regional abnormalities of LV function on a global EF determination have been shown in phantom studies.[15] In the present study, 2 patients had inferior aneurysms and 2 had inferoapical aneurysms; thus, the theoretical limitation may have been masked by the presence of 6 patients with anterior aneurysms. It is also possible that the theoretical overestimation (due to exclusion of the dyskinetic region from the field of view) is balanced by the theoretical underestimation in patients with LV dilatation.[5] Most patients with aneurysm in the present study had evidence of LV dilatation as well as regional akinesia or dyskinesia.

Acknowledgment: We thank Charles Colvin for technical assistance and Geri McCausland for preparation of the manuscript.

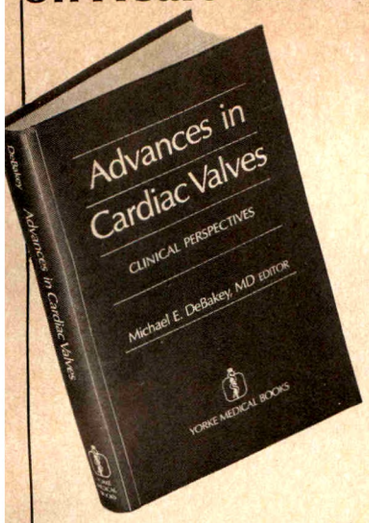
The Most Extensive Compilation of Information on Heart Valve Replacement Available Today!



Advances in Cardiac Valves
Clinical Perspectives

edited by **Michael E. DeBakey, MD**

0-914316-40-0, November 1983, 274pp., $35.00

This valuable new clinical reference provides a detailed update on many aspects of mechanical heart valve prostheses, including hemodynamics, clinical results, results in children, non-invasive assessments, special indications, and implant techniques. Each topic is presented in an easily understood style and format which facilitate the comprehension of recent developments in heart valve replacement for the busy clinician.

Each chapter is written by internationally respected physicians and medical scientists each of whom is pre-eminent in his field. All of this information has been co-ordinated by Dr. DeBakey to produce a very readable and informative volume on the state-of-the-art of heart valve replacement with mechanical prostheses. No cardiologist, cardiovascular surgeon, internist, or bioengineer can afford *not* to be knowledgeable about the information in this book.

When used with a beta blocker and a diuretic

Fewer complaints with Apresoline® hydralazine HCl

Reference

1. McAreavey D, Ramsey LE, Latham L, et al: "Third drug" trial: comparative study of antihypertensive agents added to treatment when blood pressure remains uncontrolled by a beta blocker plus thiazide diuretic. *Br Med J* 1984(Jan 14); 288:106-111.

Apresoline® hydrochloride

hydralazine hydrochloride USP

TABLETS

INDICATIONS

Essential hypertension, alone or as an adjunct.

CONTRAINDICATIONS

Hypersensitivity to hydralazine; coronary artery disease; and mitral valvular rheumatic heart disease.

WARNINGS

Hydralazine may produce in a few patients a clinical picture simulating systemic lupus erythematosus. In such patients hydralazine should be discontinued unless the benefit-to-risk determination requires continued antihypertensive therapy with this drug. Symptoms and signs usually regress when the drug is discontinued but residua have been detected many years later. Long-term treatment with steroids may be necessary.

Complete blood counts, L.E. cell preparations, and antinuclear antibody titer determinations are indicated before and periodically during prolonged therapy with hydralazine even though the patient is asymptomatic. These studies are also indicated if the patient develops arthralgia, fever, chest pain, continued malaise or other unexplained signs or symptoms.

A positive antinuclear antibody titer and/or positive L.E. cell reaction requires that the physician carefully weigh the implications of the test results against the benefits to be derived from antihypertensive therapy with hydralazine.

Use MAO inhibitors with caution in patients receiving hydralazine.

When other potent parenteral antihypertensive drugs, such as diazoxide, are used in combination with hydralazine, patients should be continuously observed for several hours for any excessive fall in blood pressure. Profound hypotensive episodes may occur when diazoxide injection and Apresoline (hydralazine hydrochloride) are used concomitantly.

Usage in Pregnancy

Animal studies indicate that hydralazine is teratogenic in mice, possibly in rabbits, and not in rats. Teratogenic effects observed were cleft palate and malformations of facial and cranial bones. Although clinical experience does not include any positive evidence of adverse effects on the human fetus, hydralazine should not be used during pregnancy unless the expected benefit clearly justifies the potential risk to the fetus.

PRECAUTIONS

Myocardial stimulation produced by Apresoline can cause anginal attacks and ECG changes of myocardial ischemia. The drug has been implicated in the production of myocardial infarction. It must, therefore, be used with caution in patients with suspected coronary artery disease.

The "hyperdynamic" circulation caused by Apresoline may accentuate specific cardiovascular inadequacies. An example is that Apresoline may increase pulmonary artery pressure in patients with mitral valvular disease. The drug may reduce the pressor responses to epinephrine. Postural hypotension may result from Apresoline, but is less common than with ganglionic blocking agents. Use with caution in patients with cerebral vascular accidents.

In hypertensive patients with normal kidneys who are treated with Apresoline, there is evidence of increased renal blood flow and a maintenance of glomerular filtration rate. In some instances improved

Fewer side-effect complaints per patient than with Aldomet® (methyldopa) or Minipress® (prazosin HCl)

—as reported in a recent study in the British Medical Journal[1]

Aldomet was responsible for an average of 4.1 complaints per patient, Minipress an average of 2.8, and Apresoline an average of 1.8.[1]

These results were obtained in a recent comparative study in which Apresoline, Aldomet and Minipress were added to the regimen of 40, 36 and 43 hypertensives, respectively, whose blood pressure had been inadequately controlled by a combination of a beta blocker and a thiazide diuretic.[1]

As with any antihypertensive agent, Apresoline should be used with caution in patients with advanced renal damage. Contraindicated in coronary artery disease.

Before prescribing, please consult Brief Summary of Prescribing Information below.

CIBA

nal function has been noted where control values ere below normal prior to Apresoline administration. However, as with any antihypertensive agent, presoline should be used with caution in patients ith advanced renal damage.

eripheral neuritis, evidenced by paresthesias, umbness, and tingling, has been observed. Published evidence suggests an antipyridoxine effect nd the addition of pyridoxine to the regimen if ymptoms develop.

lood dyscrasias, consisting of reduction in hemoobin and red cell count, leukopenia, agranulocyosis, and purpura, have been reported. If such bnormalities develop, discontinue therapy. Periodic lood counts are advised during prolonged therapy.

he Apresoline tablets (10 and 100 mg) contain D&C Yellow No. 5 (tartrazine) which may cause llergic-type reactions (including bronchial asthma) n certain susceptible individuals. Although the overll incidence of FD&C Yellow No. 5 (tartrazine) ensitivity in the general population is low, it is requently seen in patients who also have aspirin ypersensitivity.

ADVERSE REACTIONS

Adverse reactions with Apresoline are usually reversble when dosage is reduced. However, in some cases it may be necessary to discontinue the drug.

Common: Headache; palpitations; anorexia; nausea; vomiting; diarrhea; tachycardia; angina pectoris.

Less frequent: Nasal congestion; flushing; lacrimation; conjunctivitis; peripheral neuritis, evidenced by paresthesias, numbness, and tingling; edema; dizziness; tremors; muscle cramps; psychotic reactions characterized by depression, disorientation, or anxiety; hypersensitivity (including rash, urticaria, pruritus, fever, chills, arthralgia, eosinophilia, and, rarely, hepatitis); constipation; difficulty in micturition; dyspnea; paralytic ileus; lymphadenopathy; splenomegaly; blood dyscrasias, consisting of reduction in hemoglobin and red cell count, leukopenia, agranulocytosis, and purpura; hypotension; paradoxical pressor response.

DOSAGE AND ADMINISTRATION

Initiate therapy in gradually increasing dosages; adjust according to individual response. Start with 10 mg 4 times daily for the first 2 to 4 days, increase to 25 mg 4 times daily for balance of first week. For second and subsequent weeks, increase dosage to 50 mg 4 times daily. For maintenance, adjust dosage to lowest effective levels.

The incidence of toxic reactions, particularly the L.E. cell syndrome, is high in the group of patients receiving large doses of Apresoline.

In a few resistant patients, up to 300 mg Apresoline daily may be required for a significant antihypertensive effect. In such cases, a lower dosage of Apresoline combined with a thiazide, reserpine, or both may be considered. However, when combining therapy, individual titration is essential to insure the lowest possible therapeutic dose of each drug.

HOW SUPPLIED

Tablets, 10 mg (pale yellow, dry-coated); bottles of 100 and 1000.

Tablets, 25 mg (deep blue, dry-coated) and 50 mg (light blue, dry-coated); bottles of 100, 500, 1000 and Accu-Pak® blister units of 100.

Tablets, 100 mg (peach, dry-coated); bottles of 100.

Dispense in tight, light-resistant container (USP).

Important Books in Internal Medicine
From Yorke Medical Books

Rheumatology
A Primary Care Approach

Written by: Bruce M. Rothschild, MD
ISBN 0-914316-33-8, $42.50, 1982

What is Rheumatology: A Primary Care Approach?

- the primary care physicians' answer to the huge, weighty tomes on Rheumatology which offer too little on diagnosis and treatment and too much on etiology and mechanisms of disease
- a practical "how-to" desk reference to a difficult but common disease affecting over 35 million patients in the U.S. alone
- a book meant to be used regularly, not read once and stored away on a library shelf

The Acquired Immune Deficiency Syndrome (AIDS) and Infections of Homosexual Men

Edited by Pearl Ma, PhD, and Donald Armstrong, MD
0-914316-38-9, 460 pp., illus., Jan. 1984, $39.50

This book cuts through the sensationalism, innuendo, and half-truths and provides clearly and succinctly all the most important current scientific thinking from many of the most pre-eminent clinical researchers working in the field. Additional comprehensive coverage is given to a wide range of other sexually transmitted diseases of homosexual men.

Infectious Complications of Neoplastic Disease
Controversies in Management

Edited by Arthur E. Brown, MD, and Donald Armstrong, MD 0-914316-43-5, 1984, $40.00

Derived from a symposium sponsored by the Infectious Disease Service, Department of Medicine and the Department of Pediatrics, Memorial Sloan-Kettering Cancer Center, New York City, and Cornell University Medical College, New York City, this book presents the latest thinking by international authorities, all of whom were invited to present findings in their area of expertise on the diagnosis, treatment, and prevention of various bacterial, fungal, viral, and parasitic infections presenting in patients with neoplastic disease.

Infections in the Abnormal Host

Edited by Michael H. Grieco, M.D.
Text by 47 Specialists. Illustrated with 147 Drawings and Photos, 78 in Full Color
0-914316-18-4, 1,060 pp., illus., 1980, $85.00

Infections in the Abnormal Host discusses in 36 revealing chapters the mechanics of host defenses. . . the various underlying disorders and the latest treatments by chemotherapy, management of agranulocytosis, immunological reconstitution, passive and active immunotherapy, and immunostimulation.

Nosocomial Infections

Edited by Richard E. Dixon, M.D.
0-914316-24-9, 340 pp., 1981, $35.00

Based on the proceedings of the 2nd International Conference on Nosocomial Infections held August 5 - 8, 1980 in Atlanta, Georgia and sponsored by the Centers for Disease Control, this book provides between two covers the most comprehensive, in-depth study of this international problem published in 10 years.

Diabetes Mellitus

Jay S. Skyler, M.D., George F. Cahill, Jr., M.D.
ISBN 0-914316-23-0, 1980, $35.00

60 internationally prominent contributors provide in 26 papers a comprehensive overview of the current thinking on the causes, mechanisms, treatment and complications of diabetes. Featured topics include:

- The causes of diabetic inheritance
- Mechanisms of diabetes
- New developments in the treatment of diabetes
- Human insulin produced by recombinant DNA technology

Modern Drug Encyclopedia
and Therapeutic Index 16th Edition

Arthur J. Lewis, MD, Gertrude Dittus Gonzales, R.Ph., Charles L. Winek, Ph.D.
$59.00, 0-914316-21-4, 1,096 pp., 1981

The all new 16th Edition of MODERN DRUG ENCYCLOPEDIA is written especially for the practitioner who needs complete, objective information on prescription drugs.

An independent team of pharmacists and physicians has researched and edited all the facts on 3,000 prescription drugs. It passes this research on to you in an easy to absorb style that's perfectly suited to the tight schedule of a time pressed practitioner.

Topics in Hypertension

edited by John H. Laragh, M.D.
ISBN 0-914316-20-6, 1980, $59.00

Places vital knowledge on the management of the hypertensive patient in the hands of the practicing physician. 85 internationally known specialists cover in-depth recent breakthroughs in understanding, diagnosing and treating this pervasive disease.

For successful monotherapy in angina*...

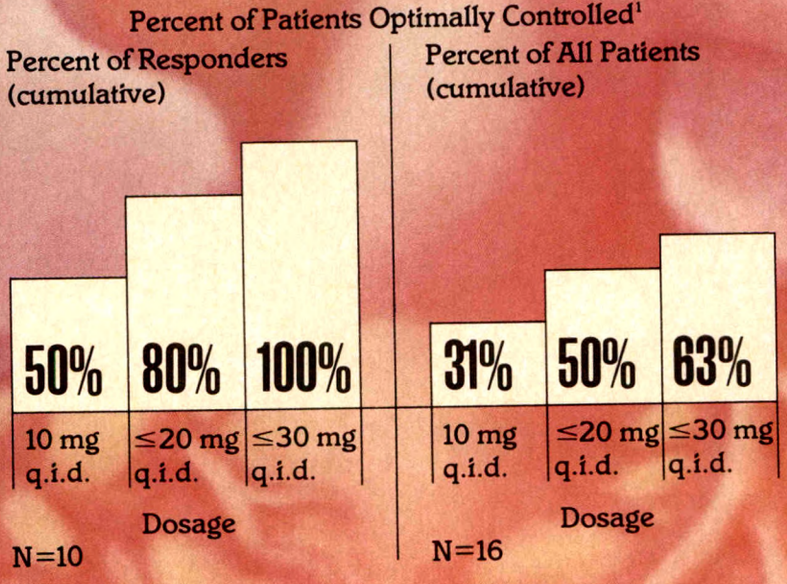
Recent evidence[1] has shown that optimal results with ISORDIL (isosorbide dinitrate) are achieved when the entire dosage range is utilized: **Start with 10 or 20 mg q.i.d. before meals and at bedtime and increase to 30 mg q.i.d. or until an optimal result is obtained. *Isordil® Titradose® has been approved for use at 40 mg q.i.d.***

ISORDIL® TITRADOSE®

(ISOSORBIDE DINITRATE) (E.Z. Split®†) Oral Tablets: 40 mg, 30 mg, 20 mg, and 10 mg

ANNOUNCING NEW 40-mg TITRADOSE® TABLETS

Effects of upward dosage titration in a double-blind cross-over study of patients with angina pectoris in whom ISORDIL reduced the number of anginal attacks by 50% or more.



†US Pat Nos. 3883647 and D224591 (Titradose®)

1.Hill JA, Feldman RL, Pepine CJ, Conti CR: Randomized double-blind comparison of nifedipine and isosorbide dinitrate in patients with coronary arterial spasm. *Am J Cardiol* 1982; 49:431-438.

© 1984 Ives Laboratories Inc.

For Brief Summary please see following page.

*ISORDIL has been evaluated as possibly effective when taken orally for this indication. See Brief Summary.

Ives®

In angina pectoris*...

Give enough to do the job

ISORDIL®
(ISOSORBIDE DINITRATE)

*Indications: Based on a review of this drug by the National Academy of Sciences—National Research Council and/or other information, FDA has classified the indications as follows:
"Possibly" effective: When taken by the oral route, Isordil is indicated for the relief of angina pectoris (pain of coronary artery disease). It is not intended to abort the acute anginal episode but is widely regarded as useful in the prophylactic treatment of angina pectoris.
Final classification of the less-than-effective indications requires further investigation.

Contraindication: Idiosyncrasy to this drug.

Warnings: Data supporting the use of nitrites and nitrates during the early days of the acute phase of myocardial infarction (the period during which clinical and laboratory findings are unstable) are insufficient to establish safety.

Precautions: Tolerance to this drug and cross-tolerance to other nitrites and nitrates may occur. In patients with functional or organic gastrointestinal hypermotility or malabsorption syndrome, it is suggested that Isordil Tembids **capsules** be the preferred therapy since a few patients have reported passing partially dissolved Isordil Tembids **tablets** in their stools; this phenomenon is believed to be on the basis of physiologic variability and to reflect rapid gastrointestinal transit of the tablet.

Adverse Reactions: Cutaneous vasodilation with flushing. Headache is common and may be severe and persistent. Transient episodes of dizziness and weakness as well as other signs of cerebral ischemia associated with postural hypotension may occasionally develop. This drug can act as a physiological antagonist to norepinephrine, acetylcholine, histamine, and many other agents. An occasional individual exhibits marked sensitivity to the hypotensive effects of nitrite, and severe responses (nausea, vomiting, weakness, restlessness, pallor, perspiration and collapse) can occur even with the usual therapeutic dose. Alcohol may enhance this effect. Drug rash and/or exfoliative dermatitis may occasionally occur.

Consult direction circular before prescribing.

Clinical Echocardiography

Hemodynamic and Pathological Correlations

by José Missri, MD

0-914316-41-9, 282 pages, 173 illus., Oct. '84, $45.00

Dr. Missri has produced a unique contribution to the further understanding and application of Doppler echocardiography in the clinical practice of medicine. This book provides the reader with ready access to a body of knowledge so logically and clearly presented that its practical utility is undeniable. Enhanced by 139 halftones, 16 line drawings and 18 tables, the information contained within its concise 282 pages is easily absorbed. And the 315 references cited not only support the material presented but serve as an excellent guide to anyone interested in further in-depth reading.

Table of Contents in brief

PRINCIPLES OF ECHOCARDIOGRAPHY AND ECHOCARDIOGRAPHIC ANATOMY
DOPPLER ECHOCARDIOGRAPHY
AORTIC VALVE DISEASE
MITRAL VALVE DISEASE
TRICUSPID VALVE DISEASE
CARDIOMYOPATHY
ISCHEMIC HEART DISEASE AND ACUTE MYOCARDIAL INFARCTION
PERICARDIAL DISEASE
INFECTIVE ENDOCARDITIS
PROSTHETIC VALVE MALFUNCTION
CONGENITAL HEART DISEASE IN THE ADULT
DISEASE OF THE AORTA
CARDIAC TUMORS

From the publishers of The American Journal of Cardiology, The American Journal of Medicine and The American Journal of Surgery . . .

The most important and best read annual publication on cardiology.

What is CARDIOLOGY 1984?

- ☐ The fourth in an annual series to be published in the summer each year — over 750 papers
- ☐ A review of the year's newest and most important developments in cardiology
- ☐ A **multidisciplinary** approach to clinical and applied research based on an exhaustive search of the year's literature
- ☐ A unique, cohesive summary of the state-of-the-art, **written,** not edited, by those making outstanding developments in the field
- ☐ A practical approach to a complicated and fast-moving subject designed to be read and used daily

Cardiology 1984 provides in a concise and readable format and style fundamental and new information essential to understanding the current thinking on managing cardiovascular disease. It coordinates what's new with well established data, arming the reader with a perspective on the field which is simply unavailable elsewhere. Its liberal use of illustrations and tables condenses valuable information into instantly understandable knowledge.

Angina Protection with Benefits for a Lifetime

ONCE-DAILY CONTROL WITH HEART-SAVING BENEFITS

By reducing heart rate and cardiac contractility, INDERAL LA helps protect the heart from the potentially serious and debilitating consequences of ischemia. A highly effective antianginal agent for around-the-clock control of symptoms, INDERAL LA also provides cardiovascular protection for a sense of security in the years ahead.

PROTECTION AND EXPERIENCE NO CALCIUM BLOCKER CAN MATCH

Unlike calcium blockers, INDERAL LA—either alone or with a nitrate—is recommended for early treatment of angina in the majority of patients. Equally important, INDERAL LA delivers the proven performance and safety profile of INDERAL tablets—confirmed by millions of patients during 16 years of clinical use.

START WITH 80 MG ONCE DAILY

Dosage may be increased to 160 mg once daily, as needed, to achieve optimal control. INDERAL LA should not be used in congestive heart failure, sinus bradycardia, cardiogenic shock, heart block greater than first degree, and bronchial asthma. Please see next page for further details and brief summary of prescribing information.

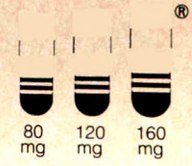
ONCE-DAILY **INDERAL® LA** (PROPRANOLOL HCl) *LONG ACTING CAPSULES*

Ayerst

The appearance of INDERAL LA capsules is a registered trademark of Ayerst Laboratories.

JUST ONCE EACH DAY FOR SIMPLIFIED CORE THERAPY IN ANGINA

ONCE-DAILY INDERAL® LA (PROPRANOLOL HCl) LONG ACTING CAPSULES



BRIEF SUMMARY *(FOR FULL PRESCRIBING INFORMATION, SEE PACKAGE CIRCULAR.)*
INDERAL® LA brand of propranolol hydrochloride **(Long Acting Capsules)**
DESCRIPTION. Inderal LA is formulated to provide a sustained release of propranolol hydrochloride. Inderal LA is available as 80 mg, 120 mg, and 160 mg capsules.
CLINICAL PHARMACOLOGY. INDERAL is a nonselective beta-adrenergic receptor blocking agent possessing no other autonomic nervous system activity. It specifically competes with beta-adrenergic receptor stimulating agents for available receptor sites. When access to beta-receptor sites is blocked by INDERAL, the chronotropic, inotropic, and vasodilator responses to beta-adrenergic stimulation are decreased proportionately.

INDERAL LA Capsules (80, 120, and 160 mg) release propranolol HCl at a controlled and predictable rate. Peak blood levels following dosing with INDERAL LA occur at about 6 hours and the apparent plasma half-life is about 10 hours. When measured at steady state over a 24-hour period the areas under the propranolol plasma concentration-time curve (AUCs) for the capsules are approximately 60% to 65% of the AUCs for a comparable divided daily dose of INDERAL tablets. The lower AUCs for the capsules are due to greater hepatic metabolism of propranolol, resulting from the slower rate of absorption of propranolol. Over a twenty-four (24) hour period, blood levels are fairly constant for about twelve (12) hours then decline exponentially.

INDERAL LA should not be considered a simple mg for mg substitute for conventional propranolol and the blood levels achieved do not match (are lower than) those of two to four times daily dosing with the same dose. When changing to INDERAL LA from conventional propranolol, a possible need for retitration upwards should be considered especially to maintain effectiveness at the end of the dosing interval. In most clinical settings, however, such as hypertension or angina where there is little correlation between plasma levels and clinical effect, INDERAL LA has been therapeutically equivalent to the same mg dose of conventional INDERAL as assessed by 24-hour effects on blood pressure and on 24-hour exercise responses of heart rate, systolic pressure and rate pressure product. INDERAL LA can provide effective beta blockade for a 24-hour period.

The mechanism of the antihypertensive effect of INDERAL has not been established. Among the factors that may be involved in contributing to the antihypertensive action are (1) decreased cardiac output, (2) inhibition of renin release by the kidneys, and (3) diminution of tonic sympathetic nerve outflow from vasomotor centers in the brain. Although total peripheral resistance may increase initially, it readjusts to or below the pretreatment level with chronic use. Effects on plasma volume appear to be minor and somewhat variable. INDERAL has been shown to cause a small increase in serum potassium concentration when used in the treatment of hypertensive patients.

In angina pectoris, propranolol generally reduces the oxygen requirement of the heart at any given level of effort by blocking the catecholamine-induced increases in the heart rate, systolic blood pressure, and the velocity and extent of myocardial contraction. Propranolol may increase oxygen requirements by increasing left ventricular fiber length, end diastolic pressure and systolic ejection period. The net physiologic effect of beta-adrenergic blockade is usually advantageous and is manifested during exercise by delayed onset of pain and increased work capacity.

In dosages greater than required for beta blockade, INDERAL also exerts a quinidine-like or anesthetic-like membrane action which affects the cardiac action potential. The significance of the membrane action in the treatment of arrhythmias is uncertain.

The mechanism of the antimigraine effect of propranolol has not been established. Beta-adrenergic receptors have been demonstrated in the platelets of the brain.

Beta receptor blockade can be useful in conditions in which, because of pathologic or functional changes, sympathetic activity is detrimental to the patient. But there are also situations in which sympathetic stimulation is vital. For example, in patients with severely damaged hearts, adequate ventricular function is maintained by virtue of sympathetic drive which should be preserved. In the presence of AV block, greater than first degree, beta blockade may prevent the necessary facilitating effect of sympathetic activity on conduction. Beta blockade results in bronchial constriction by interfering with adrenergic bronchodilator activity which should be preserved in patients subject to bronchospasm.

Propranolol is not significantly dialyzable.
INDICATIONS AND USAGE. Hypertension: INDERAL LA is indicated in the management of hypertension; it may be used alone or used in combination with other antihypertensive agents, particularly a thiazide diuretic. INDERAL LA is not indicated in the management of hypertensive emergencies.

Angina Pectoris Due to Coronary Atherosclerosis: INDERAL LA is indicated for the long-term management of patients with angina pectoris.

Migraine: INDERAL LA is indicated for the prophylaxis of common migraine headache. The efficacy of propranolol in the treatment of a migraine attack that has started has not been established and propranolol is not indicated for such use.

Hypertrophic Subaortic Stenosis: INDERAL LA is useful in the management of hypertrophic subaortic stenosis, especially for treatment of exertional or other stress-induced angina, palpitations, and syncope. INDERAL LA also improves exercise performance. The effectiveness of propranolol hydrochloride in this disease appears to be due to a reduction of the elevated outflow pressure gradient which is exacerbated by beta-receptor stimulation. Clinical improvement may be temporary.
CONTRAINDICATIONS. INDERAL is contraindicated in 1) cardiogenic shock; 2) sinus bradycardia and greater than first degree block; 3) bronchial asthma; 4) congestive heart failure (see WARNINGS) unless the failure is secondary to a tachyarrhythmia treatable with INDERAL.
WARNINGS. CARDIAC FAILURE: Sympathetic stimulation may be a vital component supporting circulatory function in patients with congestive heart failure, and its inhibition by beta blockade may precipitate more severe failure. Although beta blockers should be avoided in overt congestive heart failure, if necessary, they can be used with close follow-up in patients with a history of failure who are well compensated and are receiving digitalis and diuretics. Beta-adrenergic blocking agents do not abolish the inotropic action of digitalis on heart muscle.

IN PATIENTS WITHOUT A HISTORY OF HEART FAILURE, continued use of beta blockers can, in some cases, lead to cardiac failure. Therefore, at the first sign or symptom of heart failure, the patient should be digitalized and/or treated with diuretics, and the response observed closely, or INDERAL should be discontinued (gradually, if possible).

IN PATIENTS WITH ANGINA PECTORIS, there have been reports of exacerbation of angina and, in some cases, myocardial infarction, following abrupt discontinuance of INDERAL therapy. Therefore, when discontinuance of INDERAL is planned the dosage should be gradually reduced over at least a few weeks, and the patient should be cautioned against interruption or cessation of therapy without the physician's advice. If INDERAL therapy is interrupted and exacerbation of angina occurs, it usually is advisable to reinstitute INDERAL therapy and take other measures appropriate for the management of unstable angina pectoris. Since coronary artery disease may be unrecognized, it may be prudent to follow the above advice in patients considered at risk of having occult atherosclerotic heart disease who are given propranolol for other indications.

Nonallergic Bronchospasm (e.g., chronic bronchitis, emphysema)—PATIENTS WITH BRONCHOSPASTIC DISEASES SHOULD IN GENERAL NOT RECEIVE BETA BLOCKERS. INDERAL should be administered with caution since it may block bronchodilation produced by endogenous and exogenous catecholamine stimulation of beta receptors.

MAJOR SURGERY: The necessity or desirability of withdrawal of beta-blocking therapy prior to major surgery is controversial. It should be noted, however, that the impaired ability of the heart to respond to reflex adrenergic stimuli may augment the risks of general anesthesia and surgical procedures.

INDERAL (propranolol HCl), like other beta blockers, is a competitive inhibitor of beta-receptor agonists and its effects can be reversed by administration of such agents, e.g., dobutamine or isoproterenol. However, such patients may be subject to protracted severe hypotension. Difficulty in starting and maintaining the heartbeat has also been reported with beta blockers.

DIABETES AND HYPOGLYCEMIA: Beta-adrenergic blockade may prevent the appearance of certain premonitory signs and symptoms (pulse rate and pressure changes) of acute hypoglycemia in labile insulin-dependent diabetes. In these patients, it may be more difficult to adjust the dosage of insulin.

THYROTOXICOSIS: Beta blockade may mask certain clinical signs of hyperthyroidism. Therefore, abrupt withdrawal of propranolol may be followed by an exacerbation of symptoms of hyperthyroidism, including thyroid storm. Propranolol does not distort thyroid function tests.

IN PATIENTS WITH WOLFF-PARKINSON-WHITE SYNDROME, several cases have been reported in which, after propranolol, the tachycardia was replaced by a severe bradycardia requiring a demand pacemaker. In one case this resulted after an initial dose of 5 mg propranolol.
PRECAUTIONS. *General:* Propranolol should be used with caution in patients with impaired hepatic or renal function. INDERAL is not indicated for the treatment of hypertensive emergencies.

Beta adrenoreceptor blockade can cause reduction of intraocular pressure. Patients should be told that INDERAL may interfere with the glaucoma screening test. Withdrawal may lead to a return of increased intraocular pressure.

Clinical Laboratory Tests: Elevated blood urea levels in patients with severe heart disease, elevated serum transaminase, alkaline phosphatase, lactate dehydrogenase.

DRUG INTERACTIONS: Patients receiving catecholamine-depleting drugs such as reserpine should be closely observed if INDERAL is administered. The added catecholamine-blocking action may produce an excessive reduction of resting sympathetic nervous activity which may result in hypotension, marked bradycardia, vertigo, syncopal attacks, or orthostatic hypotension.

Carcinogenesis, Mutagenesis, Impairment of Fertility: Long-term studies in animals have been conducted to evaluate toxic effects and carcinogenic potential. In 18-month studies in both rats and mice, employing doses up to 150 mg/kg/day, there was no evidence of significant drug-induced toxicity. There were no drug-related tumorigenic effects at any of the dosage levels. Reproductive studies in animals did not show any impairment of fertility that was attributable to the drug.

Pregnancy: Pregnancy Category C. INDERAL has been shown to be embryotoxic in animal studies at doses about 10 times greater than the maximum recommended human dose. There are no adequate and well-controlled studies in pregnant women. INDERAL should be used during pregnancy only if the potential benefit justifies the potential risk to the fetus.

Nursing Mothers: INDERAL is excreted in human milk. Caution should be exercised when INDERAL is administered to a nursing woman.

Pediatric Use: Safety and effectiveness in children have not been established.
ADVERSE REACTIONS. Most adverse effects have been mild and transient and have rarely required the withdrawal of therapy.

Cardiovascular: bradycardia; congestive heart failure; intensification of AV block; hypotension; paresthesia of hands; thrombocytopenic purpura; arterial insufficiency, usually of the Raynaud type.

Central Nervous System: lightheadedness; mental depression manifested by insomnia, lassitude, weakness, fatigue; reversible mental depression progressing to catatonia; visual disturbances; hallucinations; an acute reversible syndrome characterized by disorientation for time and place, short-term memory loss, emotional lability, slightly clouded sensorium, and decreased performance on neuropsychometrics.

Gastrointestinal: nausea, vomiting, epigastric distress, abdominal cramping, diarrhea, constipation, mesenteric arterial thrombosis, ischemic colitis.

Allergic: pharyngitis and agranulocytosis, erythematous rash, fever combined with aching and sore throat, laryngospasm and respiratory distress.

Respiratory: bronchospasm.

Hematologic: agranulocytosis, nonthrombocytopenic purpura, thrombocytopenic purpura.

Auto-Immune: In extremely rare instances, systemic lupus erythematosus has been reported.

Miscellaneous: alopecia, LE-like reactions, psoriasiform rashes, dry eyes, male impotence, and Peyronie's disease have been reported rarely. Oculomucocutaneous reactions involving the skin, serous membranes and conjunctivae reported for a beta blocker (practolol) have not been associated with propranolol.
DOSAGE AND ADMINISTRATION. INDERAL LA provides propranolol hydrochloride in a sustained-release capsule for administration once daily. If patients are switched from INDERAL tablets to INDERAL LA capsules, care should be taken to assure that the desired therapeutic effect is maintained. INDERAL LA should not be considered a simple mg for mg substitute for INDERAL. INDERAL LA has different kinetics and produces lower blood levels. Retitration may be necessary especially to maintain effectiveness at the end of the 24-hour dosing interval.

HYPERTENSION—*Dosage must be individualized.* The usual initial dosage is 80 mg INDERAL LA once daily, whether used alone or added to a diuretic. The dosage may be increased to 120 mg once daily or higher until adequate blood-pressure control is achieved. The usual maintenance dosage is 120 to 160 mg once daily. In some instances a dosage of 640 mg may be required. The time needed for full hypertensive response to a given dosage is variable and may range from a few days to several weeks.

ANGINA PECTORIS—*Dosage must be individualized.* Starting with 80 mg INDERAL LA once daily, dosage should be gradually increased at three to seven day intervals until optimum response is obtained. Although individual patients may respond at any dosage level, the average optimum dosage appears to be 160 mg once daily. In angina pectoris, the value and safety of dosage exceeding 320 mg per day have not been established.

If treatment is to be discontinued, reduce dosage gradually over a period of a few weeks (see WARNINGS).

MIGRAINE—*Dosage must be individualized.* The initial oral dose is 80 mg INDERAL LA once daily. The usual effective dose range is 160-240 mg once daily. The dosage may be increased gradually to achieve optimum migraine prophylaxis. If a satisfactory response is not obtained within four to six weeks after reaching the maximum dose, INDERAL LA therapy should be discontinued. It may be advisable to withdraw the drug gradually over a period of several weeks.

HYPERTROPHIC SUBAORTIC STENOSIS—80-160 mg INDERAL LA once daily.

PEDIATRIC DOSAGE—At this time the data on the use of the drug in this age group are too limited to permit adequate directions for use.

*The appearance of INDERAL LA capsules is a registered trademark of Ayerst Laboratories.

Association of Methemoglobinemia and Intravenous Nitroglycerin Administration

KERRY J. KAPLAN, MD, MARK TABER, MD, J. RUSSELL TEAGARDEN, RPh, MICHELE PARKER, RN, MS, and RICHARD DAVISON, MD

Significant elevation of arterial methemoglobin levels has been reported with the administration of intravenous (i.v.) nitroglycerin (NTG). To determine the incidence and clinical significance of this side effect of i.v. NTG, serial arterial methemoglobin levels were determined in 50 consecutive patients receiving i.v. NTG for 48 hours or longer. The mean i.v. NTG infusion rate was 290 ± 13 μg/min (4.1 ± 0.2 μg/kg/min) and the mean duration of infusion was 7.1 ± 0.5 days. The mean methemoglobin level for the 141 samples was 1.57 ± 0.08%, which differs from the control mean value in our laboratory of 0.44 ± 0.01%. Although no patient had clinical symptoms from methemoglobin, 20 patients had elevated (>1%) levels on at least 1 measurement. Seventy-eight of the 141 samples analyzed were in the normal range; 63 determinations were between 2 and 5%. Patients with normal methemoglobin levels differed from those with abnormal levels in the dose of i.v. NTG (mean infusion rate 244 ± 16 vs 351 ± 17 μg/min; total cumulative dose 1,612 ± 153 vs 3,398 ± 308 mg). Age, weight, renal and hepatic function, and arterial oxygen saturation were not different between the groups. In conclusion, clinically significant methemoglobinemia is uncommon with i.v. NTG infusion; however, when large doses of NTG are administered, this complication is more likely. (Am J Cardiol 1985;55:181–183)

Clinically significant methemoglobinemia during the administration of organic nitrates, including intravenous (i.v.) nitroglycerin (NTG), has been reported recently.[1–3] This oxidized (ferric) form of hemoglobin cannot bind or release oxygen and causes a leftward shift in the oxyhemoglobin dissociation curve.[4,5] We undertook a prospective study to determine the frequency and clinical significance of methemoglobinemia in patients treated with i.v. NTG.

Methods

Serial methemoglobin levels were measured in 50 consecutive patients treated with i.v. NTG for at least 48 hours. NTG in concentrations of either 300 or 600 μg/ml was infused through either polyvinyl chloride or polyethylene-polypropylene tubing. The infusion rate was controlled by an IMED volumetric infusion pump. The infusion rate was started at 25 to 50 μg/min and increased as tolerated at 25- to 50-μg/min increments to control angina pectoris.[6] Topical, oral and sublingual nitrates were administered as ordered by the attending physician.

Arterial blood samples were obtained 48 to 72 hours after NTG administration was initiated and repeated at 24- to 72-hour intervals during the duration of the infusion. Samples were collected in heparinized syringes and placed on ice for immediate transport to the blood gas laboratory, where they were analyzed on an IL 282 cooximeter for methemoglobin, expressed as percent (to the nearest whole number) of total hemoglobin present in the oxidized or methemoglobin state.

Results are expressed as mean ± standard error of the mean. Standard t tests were used to compare groups.

Results

The 50 patients in the study group included 26 men and 24 women, average age 63.6 ± 1.4 years. The indication for i.v. NTG was unstable angina in 11 patients (22%) and angina after myocardial infarction in 39 patients (78%). Intravenous NTG was administered continuously for a mean of 7.1 ± 0.5 days (range 1 to 30). The mean i.v. NTG infusion rate was 290 ± 13 μg/min (range 30 to 1,000) or 4.1 ± 0.2 μg/kg/min (range 0.4 to 12.6). In addition, 43 patients were receiving NTG ointment at a mean daily dosage of 18.0 ± 1.6 inches and 33 patients were receiving isosorbide dinitrate in a mean total oral dose of 299 ± 40 mg/day.

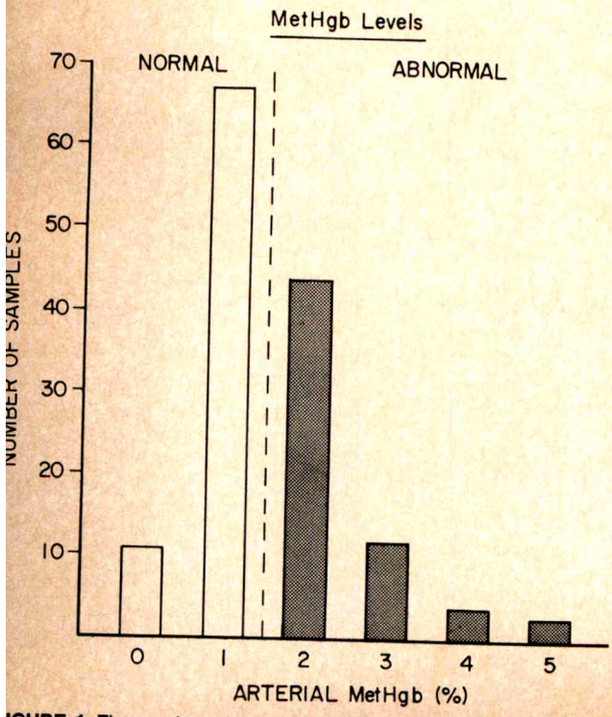
TABLE I Patient Characteristics

	Methemoglobin (0–1%) (n = 78)	Methemoglobin (2–5%) (n = 63)	p Value
Age (yr)	64 ± 1	65 ± 1	NS
Weight (kg)	76 ± 2	73 ± 1	NS
Creatinine (mg/dl)	1.2 ± 0.1	1.4 ± 0.1	<0.08
Blood urea nitrogen (mg/dl)	19 ± 0.9	20 ± 1.5	NS
Alk phos (mU/ml)	96 ± 3	105 ± 8	NS
Total bilirubin (mg/dl)	0.6 ± 0.04	0.4 ± 0.04	NS
PaO_2 (Torr)	74 ± 2	77 ± 2	NS
O_2 saturation (%)	94 ± 1	93 ± 1	NS

Alk phos = alkaline phosphatase; NS = not significant; PaO_2 = oxygen partial pressure.

A total of 141 arterial samples were analyzed for methemoglobin. The mean methemoglobin level for these samples was 1.57 ± 0.08%, which is higher than the mean normal value for our laboratory, 0.44 ± 0.01%.[7] Abnormal methemoglobin levels are defined as more than 1%, which is the mean plus 2 standard deviations. Twenty patients had abnormal methemoglobin levels on at least 1 determination, but in no instance could clinical manifestations be attributed to this finding. Methemoglobin levels ranged from 0 to 5% of total hemoglobin (Fig. 1). Seventy-eight of the 141 samples were 0 or 1% and 63 determinations were between 2 and 5%.

In an attempt to identify the factors involved in the development of elevated methemoglobin, all blood samples were classified as having normal (≤1%) or abnormal (>1%) methemoglobin levels. The patients



IGURE 1. The number of samples for each arterial methemoglobin MetHgb) level. The samples are divided into normal (0 to 1%) and bnormal (2 to 5%) values.

TABLE II Nitrate Therapy

	Methemoglobin (0–1%)	Methemoglobin (2–5%)	p Value
IV NTG μg/min	244 ± 16	351 ± 17	<0.001
μg/kg/min	3.2 ± 0.2	5.0 ± 0.3	<0.001
days	5.1 ± 0.3	9.7 ± 1.0	<0.001
mg (cumulative dose)	1,612 ± 153	3,398 ± 308	<0.001
NTG ointment (inches/day)	17 ± 1	20 ± 1	NS
Isosorbide dinitrate (mg/day)	295 ± 24	305 ± 33	NS

NS = not significant; NTG = nitroglycerin.

whose samples had normal methemoglobin levels were compared with those whose samples had abnormal methemoglobin levels. Age, weight, renal and hepatic function tests, and arterial oxygen saturation were not significantly different between the 2 groups (Table I). However, the i.v. NTG therapy at the time of sampling was different between the groups (Table II). The mean i.v. NTG infusion rate in patients with a normal methemoglobin level was 244 ± 16 μg/min, and that in patients with an elevated methemoglobin level was 351 ± 17 μg/min. The dose expressed in μg/kg/min was also significantly different. The duration of the i.v. NTG infusion was significantly longer in patients with abnormal methemoglobin levels, 9.7 ± 1.0 vs 5.1 ± 0.3 days. Predictably, the patients with elevated methemoglobin levels had a significantly greater total cumulative i.v. NTG dose (3,398 ± 308 mg) than those with normal levels (1,612 ± 153 mg). When the doses of NTG ointment or isosorbide dinitrate are compared, there is no significant difference between groups.

As the total cumulative dose of i.v. NTG increases, so does the percentage of samples with abnormal methemoglobin values (Fig. 2). For purposes of reference, a patient receiving a continuous infusion of 300 μg/min of NTG would receive approximately 450 mg/day.

After completion of the data collection for this study, a patient receiving i.v. NTG was found, in a routine arterial blood sample, to have a methemoglobin level of 12%. No clinical manifestations could be attributed to this finding. After tapering of the i.v. NTG dose, the arterial methemoglobin level rapidly returned to 0. A determination of the major methemoglobin-reducing enzyme, NADH ferricyanide reductase,*[8] revealed it to be in the normal range (patient 21.4, control 15.3, normal 19.2 ± 3.8), thus excluding the possibility of a congenital enzyme deficiency. The elevated methemoglobin level in this patient may have been the result of the simultaneous administration of i.v. NTG and phenazopyridine (Pyridium®), which is an aniline dye whose use has been associated with methemoglobinemia.[9]

Discussion

Methemoglobinemia interferes with oxygen delivery in 2 ways: (1) In the oxidized form, hemoglobin cannot release or take up oxygen,[4] and (2) its presence shifts the oxyhemoglobin dissociation curve to the left.[5] A bluish

* NADH ferricyanide reductase assays were kindly performed by Dr. E. Beutler, Scripps Institute, La Jolla, California.

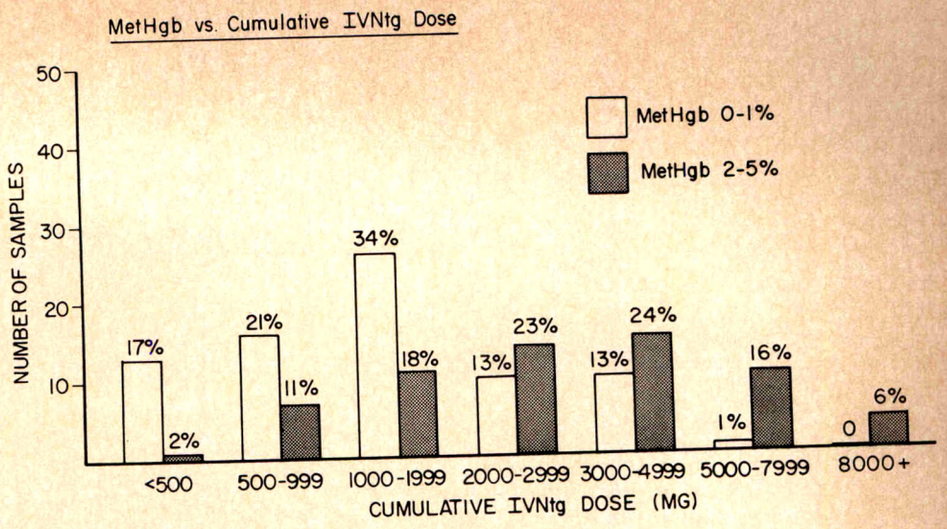


FIGURE 2. A comparison of total, cumulative dose of intravenous nitroglycerin (IVNtg) received and number of normal vs abnormal methemoglobin (MetHgb) samples. A modified logarithmic scale is used for cumulative IV NTG dose in order to make the number of samples in each range comparable. The **numbers above the bars** refer to the percentage of all normal or abnormal samples in that range of doses.

discoloration of the skin occurs at total methemoglobin levels of 1.5 g. When 30% of hemoglobin is present as methemoglobin, mild fatigue, lethargy, headache and a decrease in exercise tolerance occur. When methemoglobin levels reach 60%, symptoms of inadequate tissue oxygenation occur such as dyspnea, coma or convulsions. The lethal level of methemoglobin in humans is above 70%.[10] However, the additive effects of coexistent anemia, hypoxemia and decreased cardiac output must also be considered and in these circumstances patients could become symptomatic at lower levels.

The metabolism of NTG occurs both in the liver and at various peripheral sites, where it is metabolized by a glutathione reductase, resulting in the formation of a nitrite.[11] Nitrites convert oxyhemoglobin to methemoglobin.[4,12]

Oxyhemoglobin and methemoglobin normally occur in equilibrium in the body in a ratio of 99 to 1. This ratio may be altered by agents that increase the rate of oxidation (nitrates, sulfonamides, aniline dye derivatives) or in patients that are deficient in the enzyme necessary for reducing methemoglobin.[9,13,14]

Although NTG-induced methemoglobinemia has been reported,[1–3] the incidence and significance of this finding has been questioned in patients receiving clinically effective doses of nitrates.[15,16] The results from our study suggest that clinically significant methemoglobinemia is rare when the usual doses of i.v. NTG are used. Patients who receive i.v. NTG have higher than normal arterial methemoglobin levels, and these levels are positively correlated with the amount of i.v. NTG received; however, none of our patients had levels that approached those necessary to cause symptoms. Nevertheless, the development of abnormally elevated methemoglobin levels can reduce oxygen-carrying capacity and, thus, potentially precipitate or aggravate tissue ischemia.

In conclusion, clinically significant methemoglobinemia associated with i.v. NTG administration is uncommon; however, it should be considered when large amounts of NTG are administered, especially in association with other oxidizing agents.

Incomplete and Delayed Bioavailability of Sublingual Nitroglycerin

PATRICK K. NOONAN, PhD, and LESLIE Z. BENET, PhD

Eight healthy male volunteers received 16 doses of sublingual nitroglycerin tablets (0.4 mg). After 8 minutes, each subject rinsed out his mouth to halt the drug absorption process. The mouth rinses were assayed by high-performance liquid chromatography for residual nitroglycerin content. Each subject also received intravenous infusions of nitroglycerin so that the absolute bioavailability could be evaluated. Plasma nitroglycerin concentrations were determined using a specific and sensitive capillary gas chromatographic method capable of quantifying 25 pg/ml of nitroglycerin. The mean bioavailability (± standard deviation) of sublingual nitroglycerin, estimated from plasma concentrations, was 36.2 ± 24.9% (range 2.6 to 113%). The amount of drug not absorbed after 8 minutes, as determined from the analysis of the mouth rinses, varied from 2.7 to 65.8% (mean 31.4 ± 18.9%) of the administered sublingual dose. Mean nitroglycerin peak concentrations of 1.89 ± 1.64 ng/ml were obtained at a mean peak time of 5.3 ± 2.3 minutes. Thus, sublingual absorption is not instantaneous and can be relatively slow, with peak times of as long as 10 minutes. These data indicate that nitroglycerin pharmacokinetic values should not be estimated only from sublingual doses. Additionally, attempts to correlate pharmacodynamic measurements to sublingual doses must take into account the low and variable bioavailability and the potentially long peak times after sublingual nitroglycerin administration to patients.

(Am J Cardiol 1985;55:184–187)

Sublingual nitroglycerin is used most often for the acute relief of angina pectoris. Other investigators, when evaluating nitroglycerin pharmacokinetics, have assumed that sublingual nitroglycerin is instantaneously and completely bioavailable. Armstrong et al[1] made these assumptions when they calculated the clearance and volume of distribution of nitroglycerin from a single sublingual dose. Other researchers have used sublingual nitroglycerin as the relative bioavailability standard for other nitroglycerin dosage forms.[2,3] The "absolute" bioavailability of sublingual nitroglycerin has not been evaluated.

Methods

Eight healthy male volunteers received sublingual tablets (0.4 mg) of nitroglycerin (Nitrostat®, Parke-Davis) obtained from the hospital pharmacy of the University of California, San Francisco. All doses were obtained from 2 bottles of the same manufactured lot (JBATMA). At 0 time, a 0.4-mg nitroglycerin tablet was placed under the subject's tongue. Two drops of distilled water were added to the tablet to insure that the tablet was moistened. The subjects were instructed to maintain the tablet in the sublingual area and not to swallow it. After 8 minutes, the subjects were instructed to spit out any remaining dose, including saliva, into a glass container. Each subject then rinsed out his mouth with 50 ml of distilled water. This maneuver essentially halts the drug absorption process. The water rinse was added to the 8-minute saliva collection and assayed by high-performance liquid chromatography (HPLC) for residual nitroglycerin content. Six of the 8 volunteers received sublingual tablets on 2 different occasions, and 2 of these 6 volunteers also received a third dose.

For each sublingual dose, serial blood samples were collected at 0, 0.5, 1, 2, 3, 4, 5, 6, 8, 10, 12.5, 15, 17.5, 20, 25, 30, 45, 60, 120, 180, 240 and 360 minutes. The blood samples were immediately processed[4] and the plasma was frozen in a dry-ice bath.

Each of the 8 subjects also received intravenous infusions of nitroglycerin so that the absolute bioavailability could be evaluated. Tridil® (American Critical Care), used for the infusions, was prepared as a 100-μg/ml solution in 5% dextrose in water. Nitroglycerin was delivered through a Tridilset® (American Critical Care), which adsorbs less than 1% of a nitroglycerin dose.[5] The dose was delivered as a constant infusion using a Harvard infusion pump and a sterile 50-ml glass

±SD	...	±1.69	±6.00	±0.6

C_{ss} = steady-state nitroglycerin plasma concentration; SD = standard deviation; $T_{1/2}$ = drug half-life.

syringe. The dose was administered through a Teflon® obturator set placed in a peripheral arm vein. Blood samples were drawn through a heparin lock placed in a peripheral vein of the opposite arm, kept patent with periodic injections of heparin (67 USP units/ml) in saline solution.

Sublingual bioavailability comparisons were made relative to a planned 40-μg/min infusion rate. Two volunteers received a 40-μg/min infusion over 100 minutes. Five volunteers received a 40-μg/min infusion over 40 minutes, which was preceded by a 10-μg/min infusion for 40 minutes and a 20-μg/min infusion for 40 minutes. One subject (MD), who became hypotensive at a dose of 40 μg/min, was studied while receiving an infusion of 20 μg/min, which was preceded by a 10-μg/min infusion for 40 minutes. The infusion rate was determined in each study by assay of the infusion solution delivered by the syringe over a fixed time interval. Blood samples were drawn at 10, 20, 30 and 40 minutes after the infusion rate was established. At the conclusion of the infusion, blood samples were drawn at 1, 2, 4, 6, 10, 15, 20, 40, 60, 120, 180 and 240 minutes to determine the half-life of the drug.

Plasma nitroglycerin concentrations were measured using a specific and sensitive capillary gas chromatographic method[4] capable of quantifying 25 pg/ml nitroglycerin (coefficient of variation [CV] = 7.6%) using 1.0 ml of plasma. The nitroglycerin content of the sublingual tablets and the mouth rinses was determined using a modification of our published HPLC assay.[6] The prepacked column (Altex 5 micron, octyl (C_8), 4.6 × 150 mm) was eluted with acetonitrile:water (40:60, v/v) at a flow rate of 160 ml/hour.

Results

The average steady-state nitroglycerin plasma concentration and the measured infusion rate in each of the 8 subjects are listed in Table I, together with the clearance and half-life of the drug. Clearance after intravenous dosing is calculated as the infusion rate divided by the average steady-state plasma concentration. Marked intersubject variability in clearance is seen (CV = 44%), although good reproducibility was found in subject RD (CV = 9.8%), who was studied twice. The average nitroglycerin half-life was 2.3 ± 0.6 minutes.

Pharmacokinetic values for nitroglycerin after 16 sublingual administrations in the 8 volunteers are listed in Table II. Peak time showed marked inter- and intrasubject variability and averaged 5.3 min. Peak plasma concentration showed even greater variability (CV = 87%). Mean half-life (2.5 min) was similar to that found following intravenous dosing. The sublingual bioavailability (%F) for each dose of nitroglycerin was calculated as $(CL_{iv} \cdot AUC_s/DOSE_s) \times 100$, where CL_{iv} = the clearance determined from the intravenous infusion and AUC_s and $DOSE_s$ = the area under the plasma concentration-time curve and dose, respectively, after sublingual administration.

Because subject RD received intravenous infusions 2 times, Table II shows 2 sets of values for each sublingual dose in this subject. Calculated nitroglycerin bioavailability in all subjects ranged from 2.6 to 113%. Mean values and standard deviations are calculated using the 16 sublingual doses in the 8 subjects. Mean values did not differ markedly when only the average

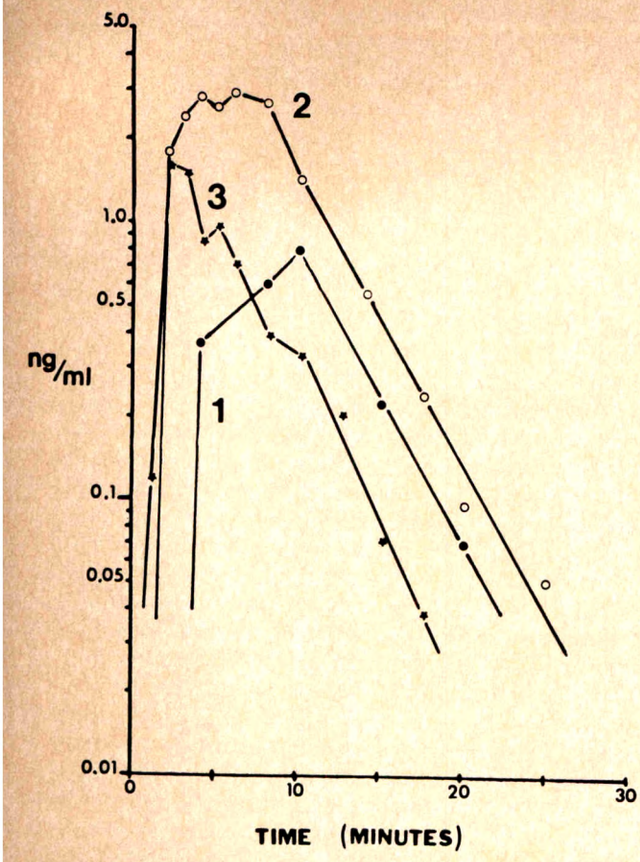

FIGURE 1. Nitroglycerin plasma concentrations after administration of a sublingual nitroglycerin tablet (0.4 mg) on 3 occasions to subject RD. The residual dose was washed out of the mouth 8 minutes after drug administration. Numerical identification corresponds to the data in Table II.

value for each subject was used in determining the means (e.g., %F = 37.5 ± 23.9). Figure 1 illustrates the marked intrasubject variability after sublingual administration on 3 different occasions.

The percent of dose measured in the mouth rinse ranged from 2.7 to 65.8% (average 31.4 ± 18.9%). Because this measurement is independent of other pharmacokinetic variables, one may conclude that sublingual dosing in this study does not yield a completely bioavailable dose of nitroglycerin. The last column in Table II is the summation of the calculated bioavailability and the measured drug in the mouth rinse. On average, 70% of the dose could be accounted for by these 2 variables, with a range from 32 to 132%. The CV for the summed parameter (37%) was less than that for the bioavailability (66%) and mouth-rinse measurements (60%). In fact, the variation in the total dose accounted for (last column, Table II) tends to reflect intersubject more than intrasubject variability. For subject RD, both bioavailability and mouth-rinse contents vary 4-fold, although the total dose accounted for remains quite constant.

Nitroglycerin tablets from each bottle were tested for potency using the HPLC assay[6] (Table III). There was no significant difference in the potency of tablets from

TABLE III Potency of 0.4-mg Nitroglycerin Tablets Obtained from Two Different Bottles of the Same Manufactured Lot

Sample	Replicate	GTN (mg)	Mean ± SD
Bottle A	1	0.51	
	2	0.44	
	3	0.42	0.44 ± 0.05
	4	0.37	
	5	0.44	
Bottle B	1	0.43

	3	0.39	
	4	0.32	0.40 ± 0.04
	5	0.39	
	6	0.45	

GTN = nitroglycerin; SD = standard deviation.

the 2 bottles. Therefore, the low bioavailability values in the subjects in this study may not be attributed to decreased tablet potency.

Discussion

The "absolute" bioavailability of sublingual nitroglycerin has not been evaluated previously. This is partly because of the uncertainty of measurements after intravenous dosing, which must be used as the bioavailability standards. The clearance values reported here (13.6 ± 6.0 liters/min, Table I) after intravenous dosing far exceed the maximum possible hepatic clearance (1.5 liters/min). Such high clearance values suggest that nitroglycerin is cleared (metabolized) by organs other than the liver. The values reported here are only about one-fourth of the extremely high venous clearance values reported by McNiff et al[7] after an 18-μg/min infusion for 32 minutes and approximately twice the arterial clearance reported by Armstrong et al[8] after a 21-μg/min infusion for 120 minutes.

However, the clearance values determined in the present study appear to give reasonable estimates of bioavailability. If we had found a clearance equal to that reported by McNiff et al,[7] bioavailability measurements would have averaged approximately 160% and total dose accounted for would have been twice the dose. The lower clearance values recently reported by Armstrong et al[8] were determined in arterial samples from patients with congestive heart failure. Both of these conditions might be expected to yield a lower clearance value; for example, patients with heart failure often have decreased drug clearance compared with normal volunteers,[9] and there is an arteriovenous nitroglycerin gradient with an extraction of about 60%.[10] Armstrong et al[10] reported arterial nitroglycerin clearance rates (13.9 ± 8.7 liters/min) in patients with heart failure almost identical to those reported herein (13.6 ± 6.0 liters/min). The differences between the values discussed above as well as possible changes in nitroglycerin clearance as a function of infusion rate and total infusion time will be addressed in another report. The times to peak nitroglycerin concentrations ranged from 2 to 10 minutes. Since these peak times range from 1 to 5 times the half-life of nitroglycerin, the absorption of a sublingual dose cannot be assumed to be instantaneous. Therefore,

estimates of the volume of distribution of nitroglycerin that assume instantaneous input of a sublingual dose will certainly be in error.

On average, 70% of the sublingual dose was accounted for as bioavailable systemic concentrations plus residual dose in the mouth (Table III). Several factors could contribute to the average 30% that was not measured: (1) Although the subjects were instructed not to swallow during the 8 minutes the tablet was in the sublingual area, this variable was not controlled. Any drug that was swallowed would be metabolized before absorption. (2) Metabolism of the drug could take place in the mucous membranes of the mouth. (3) Differences in nitroglycerin clearance may be found between the intravenous infusion doses and the sublingual administration. Previously reported data[7,8,10] and our own unpublished studies indicate that the clearance may initially appear higher than that observed after a steady state is reached. Considering these factors, the 70% value probably indicates that the method used in this study reasonably describes nitroglycerin disposition after sublingual dosing. In addition, the value for only 1 of the 16 doses is markedly greater than 100% (subject JK, dose 1).

The inter- and intrasubject variation in bioavailability may be due simply to large variability in the absorption of nitroglycerin. No difference in bioavailability was noted between tablets from the 2 bottles used, and the contents of the tablets were as labeled (Table III). Crabbs et al[11] reported that sublingual nitroglycerin tablets, with acceptable disintegration characteristics, showed slow dissolution properties. Although some tablets were completely dissolved within 2 minutes, others were still not completely dissolved after 80 minutes in the dissolution apparatus. Nitroglycerin dissolution rate will certainly play an important role in defining the rate and extent of the bioavailability of sublingual nitroglycerin tablets. Many factors independent of the dosage form may play a role in the sublingual absorption of drugs: blood flow to the sublingual membranes; the ability of the volunteer (patient) to maintain the dose in the sublingual area without swallowing; and the hydration state of the sublingual area (i.e., dry mouth), which has been reported to affect the sublingual absorption of drugs.[12]

In conclusion, this study indicates that the bioavailability of sublingual nitroglycerin may be low and variable. A substantial portion of the administered sublingual dose was recovered from the mouth rinses after 8-minutes contact time with the sublingual membranes. These data indicate that nitroglycerin pharmacokinetic values should not be estimated only from sublingual doses of nitroglycerin. Additionally, attempts to correlate pharmacodynamic measurements to sublingual doses must take into account the low and variable bioavailability and the potentially long peak times after sublingual nitroglycerin administration to patients.

Validation in Dogs of a Rapid Digital Angiographic Technique to Measure Relative Coronary Blood Flow During Routine Cardiac Catheterization

JOHN McB. HODGSON, MD, VICTOR LeGRAND, MD, ERIC R. BATES, MD, G. B. JOHN MANCINI, MD, FRED M. AUERON, MD, WILLIAM W. O'NEILL, MD, SANDRA B. SIMON, MA, GLENN J. BEAUMAN, MS, MICHAEL T. LeFREE, BS, and ROBERT A. VOGEL, MD

Assessment of the functional significance of anatomically defined coronary stenoses has been hampered by the lack of clinically applicable techniques of measuring coronary blood flow or flow ratios. A digital angiographic technique is reported that allows rapid analysis of relative regional coronary blood flow during routine cardiac catheterization. This technique was validated in dogs by comparing digital flow ratio estimates with electromagnetic-flow (EMF) ratio measurements. Fourteen open-chest dogs had EMF probes placed on the proximal left anterior descending artery before selective coronary angiography. Electrocardiographically gated images were acquired directly by a digital radiographic system during both baseline blood flow and either contrast or papaverine-induced hyperemia. Dual-parameter functional images were generated using color and intensity coding to represent contrast arrival time and contrast density, respectively. For analysis, myocardial areas of interest were created over the distal perfusion bed of the left anterior descending coronary artery. Mean contrast density/appearance time (CD/AT) values were computer calculated as the mean density divided by the mean arrival time for each. Coronary flow reserve was determined as the ratio of the CD/AT value for a hyperemic image divided by the CD/AT value for the corresponding baseline image. CD/AT ratios correlated well (r = 0.92) with actual EMF ratios (CD/AT Ratio = 0.90 EMF Ratio + 0.12, n = 48 ratios). Reproducibility was ±13%. Interobserver (r = 0.99) and intraobserver (r = 0.98) variability was excellent. Thus, rapid, accurate and reproducible estimates of relative regional coronary blood flow are possible using digital radiography. (Am J Cardiol 1985;55:188–193)

Although selective coronary arteriograms have long been the standard means of defining coronary anatomy, until recently little additional information has been available from these images. Our laboratory has described a digital angiographic technique that provides information on relative coronary blood flow and can be performed during routine cardiac catheterization.[1] Electrocardiographically gated (ECG-gated) digital images from successive cardiac cycles were used to generate dual-parameter functional images, termed contrast medium appearance pictures (CMAP). In these images, myocardial contrast appearance time is color coded, and was originally considered to be inversely proportional to blood flow. Our validation study used atrial pacing to induce hyperemia. The amount of flow during hyperemia was divided by the amount of basal flow to create coronary flow reserve ratios, and a good correlation between contrast appearance time ratios and coronary sinus blood flow ratios was demonstrated (r = 0.90) in humans.

Since that report, the technique has been refined. With current techniques, digital images are stored directly on a digital disk allowing immediate analysis without the need for initial film storage and subsequent digitization. ECG-gated power injection and atrial

pacing are now used routinely. In addition, either contrast or papaverine are used to induce hyperemia. In this report we describe the improved technique and further validation in instrumented dogs.

Methods

Animal preparation: Fourteen mongrel dogs of either sex that weighed 25 to 44 kg (average 32) were anesthetized with intravenous pentobarbital (35 mg/kg) and ventilated with room air using a Harvard respirator. A left thoracotomy was performed. Right atrial epicardial pacing electrodes were placed after the sinus node and accessory pacemaker cells were ablated by intramyocardial infiltration of a 50/50 mixture of absolute alcohol and 0.5% Marcaine® solution. This allowed atrial pacing at heart rates of less than 130 beats/min. The proximal left anterior descending coronary artery was dissected free, and an appropriately sized electromagnetic flow (EMF) probe (Carolina Medical Electronics, model EP200®) and pneumatic cuff occluder were placed. The EMF was calibrated by timed collection and corrected for hematocrit. Selective coronary catheterization was performed using a 7Fr Amplatz catheter introduced retrogradely through a right femoral artery sheath under fluoroscopic guidance.

Image acquisition: Atrial pacing was used throughout image acquisition at a rate just above the intrinsic rate. Images were stored directly on a digital disk using ECG-gated cineradiographic mode acquisition, fixed kilovoltage, amperage, pulse width (approximately 70 kV, 200 mA, and 5 ms, respectively), and logarithmic analog-to-digital conversion. The image matrix was 512 × 512 × 8 bits. Imaging was performed with cineradiographic equipment (Philips model Optimus M200) interfaced directly to a digital radiographic computer (ADAC, model DPS-4100). All image acquisition was ECG gated to provide 2 images per cardiac cycle at 50% and 75% of the RR interval (intended to correspond to cardiac diastasis). Full-strength sodium meglumine diatrizoate (Renografin 76®, Squibb & Sons) was injected using an ECG-gated angiographic power injector (Mark IV®, Medrad). Three milliliters were delivered at 3 ml/s for all image acquisitions. Images were obtained during baseline flow (obtained at least 3 minutes after previous contrast administration) and during hyperemia induced by intracoronary contrast injections (0.5 to 5 ml) 10 to 15 seconds before imaging (n = 29), or intracoronary papaverine (5 mg) delivered 30 to 45 seconds before imaging (n = 3).

Image processing: Images were processed by mask-mode subtraction. The last single frame before contrast administration was chosen as the mask. Five to 8 successive diastolic images were selected as the image subset (1 per cardiac cycle), and standard mask-mode subtraction was accomplished. Dual-parameter functional images were then generated using a threshold (8%) criterion, which assigns pixel color based on the number of cardiac cycles after injection at which the given pixel density must exceed the threshold. Red was assigned to pixels that had an intensity that surpassed the threshold in the first postinjection cycle, yellow for the second cycle, white for the third, green for the fourth, and so on. All studies from a dog were generated using the same number of images. The intensity of each pixel in the functional image was defined by the maximal density achieved during that series.

Image analysis: Regional flow ratios were quantitatively determined from CMAP pairs using the videodensitometric[2,3] principle:

$$\dot{Q} = \frac{RVV}{t} \quad (1)$$

where $\dot{Q}$ = regional blood flow, RVV = regional vascular volume, and t = transit time. This laboratory initially used the assumption that regional vascular volume (RVV) remained constant under baseline and hyperemic conditions. Under this

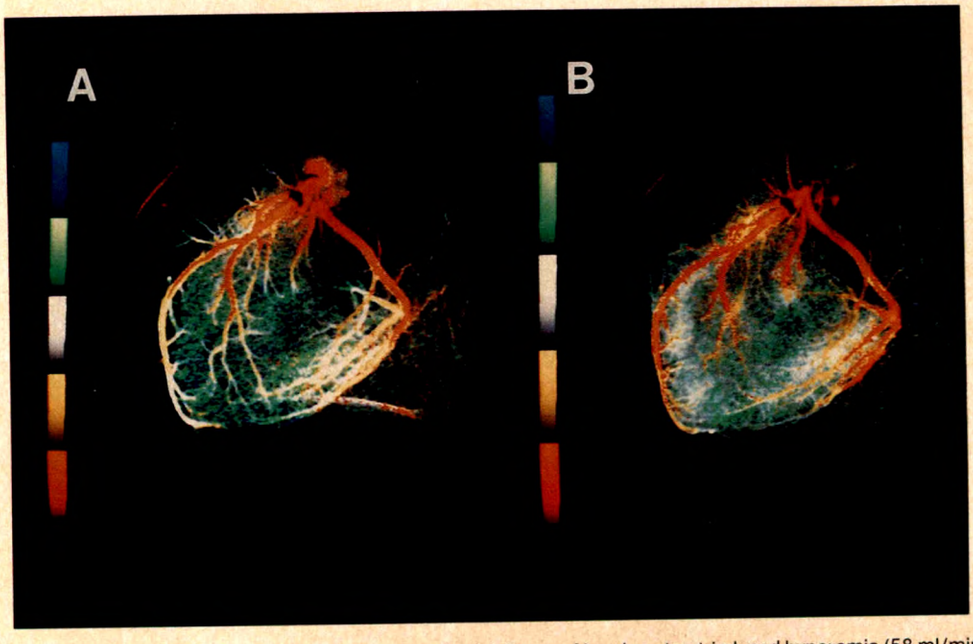

FIGURE 1. Functional images from a dog during baseline flow (27 ml/min) (**image A**) and contrast-induced hyperemia (58 ml/min) (**image B**). Note the earlier colors and greater intensity over the distribution of the left anterior descending artery in **image B.** The appearance time (AT) value for **image A** is 1.89 second and that for **image B** is 1.26 second. The contrast density/appearance time (CD/AT) values are 0.13 and 0.29, respectively. The flow reserve ratio determined by electromagnetic flow probe is 2.15. The flow reserve ratio measured digitally is 1.50 using the AT values alone and 2.23 using the CD/AT values.

assumption, $\dot{Q}_h/\dot{Q}_b$ was determined using mean arrival time (AT) as the transit time parameter:

$$\frac{\dot{Q}_h}{\dot{Q}_b} = \frac{RVV/AT_h}{RVV/AT_b} = \frac{AT_b}{AT_h} \quad (2)$$

This approach yielded a close correlation between pacing-induced hyperemic-to-baseline flow ratios measured by digital radiography and thermodilution measurements of coronary sinus and great cardiac vein blood flow.[1] Application of this principle to contrast medium–induced hyperemic-to-baseline blood flow ratio determinations, however, yielded substantial underestimation of high flow ratios. This was attributed to RVV increases caused by the hyperemia-inducing stimulus. Therefore, we estimated RVV using logarithmic mask-mode subtraction[4,5] and the equation:

$$RVV = \frac{k}{c} \int D \quad (3)$$

where k = radiographic constant, c = contrast medium concentration, and D = radiographic density. The radiographic constant (k) is a function of the attenuation coefficient of the iodine medium, the transfer function of the image intensifier and plumbicon, the radiographic parameters used, and the analog-to-digital conversion function.[6] For measurements of relative RVV changes under conditions of 100% contrast medium concentration, k and c cancel out. Similarly, if the same regions of interest are used for baseline and hyperemic conditions, mean contrast density (CD) can be substituted, yielding:

$$\frac{\dot{Q}_h}{\dot{Q}_b} = \frac{\frac{k}{c}\int D_h/AT_h}{\frac{k}{c}\int D_b/AT_b} = \frac{CD_h}{AT_h} \div \frac{CD_b}{AT_b} \quad (4)$$

Mean (arithmetic) contrast medium appearance time and density were computer histographically determined within operator-defined left anterior descending coronary artery areas of interest for each CMAP. These regions contained 3,000 to 5,000 pixels and were placed in such a way as to exclude the large epicardial arteries, the aortic root and the coronary sinus. Equivalent regions were chosen for each picture pair. Only the studies obtained within 10 minutes of each other were used for flow ratio determinations. Hyperemia-to-baseline and baseline-to-baseline flow ratios were calculated using equation 4 and were compared to EMF flow ratios of mean values obtained at the onset of injection. Because the CMAP analysis yields appearance time in cardiac cycle units, these values were converted to seconds using the cycle length. In this calculation, pixels appearing in the first cardiac cycle after contrast administration were assigned an AT of 0.5 cycles, those in the second cycle an AT of 1.5 cycles, and so on.

Statistical analysis: Least-squares linear regression was used to compare the digital AT and CD/AT ratios and the actual EMF ratios. Reproducibility was assessed by comparing ratios of successive baseline images and was calculated as the mean difference between corresponding AT ratios and EMF ratios divided by the mean EMF ratio for all comparisons. Inter- and intraobserver variability were calculated as the standard error of the estimate (SEE) of a least-squares linear regression comparing sequential observations.

Results

Animal validation: Figure 1 shows 2 functional images from the same dog. Image A was obtained at baseline blood flow (27 ml/min) and image B during contrast-induced hyperemia (58 ml/min). The AT value for image A is 1.89 s and for image B 1.26 s. The CD/AT value for image A is 0.13 and for image B 0.29. The EMF coronary flow reserve ratio is 2.15. The coronary flow reserve ratio measured digitally is 1.5 using AT data alone, but 2.23 using the CD/AT ratio.

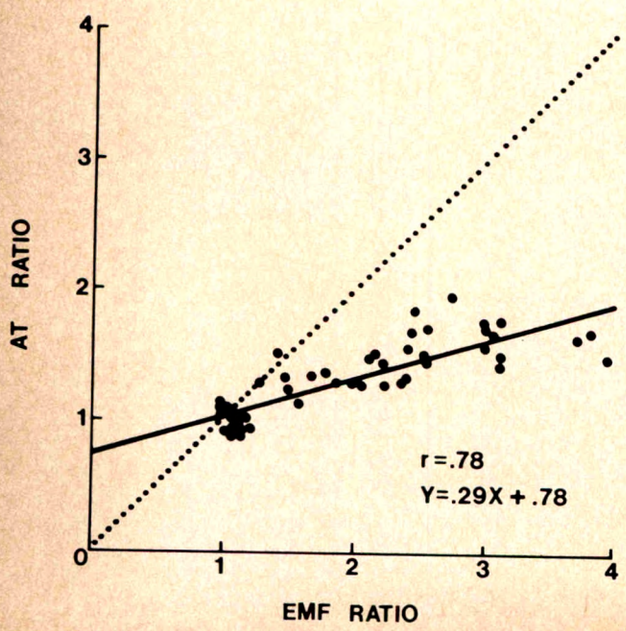

FIGURE 2. Correlation of coronary flow reserve ratios measured by electromagnetic flow (EMF) probe and ratios calculated from digital estimates using appearance time (AT) (in seconds) only. Despite a fair correlation, digital AT ratios considerably underestimated true flow ratios.

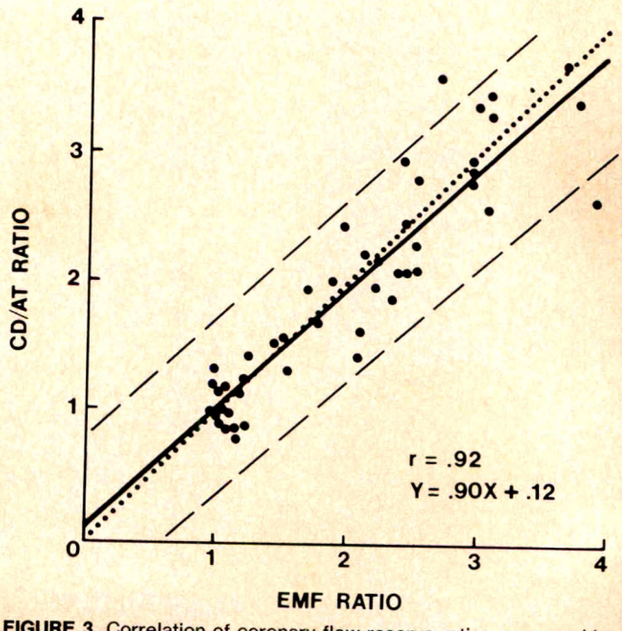

FIGURE 3. Correlation of coronary flow reserve ratios measured by electromagnetic flow (EMF) probe and ratios calculated digitally using both contrast density and appearance time (CD/AT) (in seconds) information. Confidence limits (95%) are represented by the **dashed lines.** Digital CD/AT ratios correlated well with EMF ratios and were more accurate than appearance time ratios alone.

TABLE I Results of Successive Baseline Blood Flow Determinations

Pair No.	EMF Ratio	CD/AT Ratio	EMF − CD/AT
1	1.00	1.00	0
2	1.00	1.05	0.05
3	1.04	1.17	0.13
4	1.04	0.93	0.11
5	1.04	0.93	0.11
6	1.10	0.86	0.24
7	1.11	1.18	0.07
8	1.05	0.88	0.17
9	1.17	1.40	0.23
10	1.10	1.39	0.29
11	1.14	1.10	0.14
12	1.00	1.36	0.36
13	1.09	1.01	0.08
14	1.05	0.91	0.14
15	1.00	1.02	0.02
Mean	1.06	1.08	0.14

Variability is 13.2% (mean EMF − [CD/AT]/mean EMF ratio).

Ratios of AT values for myocardial areas of interest showed a fair correlation with actual flow ratios ($r = 0.78$). Forty-eight ratios were obtained from a total of 65 images in the 14 dogs. Only CMAPs obtained within 10 minutes of each other were used for flow ratios (Fig. 2). The regression equation is $y = 0.29x + 0.78$, where y is the ratio of AT values and x the ratio of EMF values. Ratios of CD/AT values for myocardial areas of interest showed a better correlation with the actual flow ratios ($r = 0.92$) (Fig. 3). The regression equation is $y = 0.90x + 0.12$, where y is the ratio of CD/AT values and x the ratio of EMF values. Reproducibility was assessed by comparison of successive baseline images within each dog. The corresponding EMF and AT ratios are shown in Table I. Reproducibility was calculated as ±13.2%.

Interobserver variability is shown in Figure 4. Two observers separately and independently viewed 28 images and generated 22 AT ratios using the computer algorithm described previously. Correlation was excellent ($r = 0.99$). The regression equation is described as the AT of observer 2 = 0.98 × AT of observer 1 + 0.01. The SEE was 0.038. Intraobserver variability is shown in Figure 5. One observer viewed 28 images and generated 22 AT ratios using the computer algorithm on 2 occasions 2 weeks apart. An excellent correlation was found ($r = 0.98$). The regression equation is described as AT (reading 2) = 1.02 × AT reading of observer 1 − 0.03. The SEE was 0.049.

Discussion

Several methodologic changes in this digital radiographic approach to measuring relative regional coronary blood flow from that originally reported by this laboratory[1] should be emphasized: (1) The current hardware allows direct digital image acquisition without prior film storage. (2) Atrial pacing is used routinely to ensure a constant heart rate during image acquisition. (3) Contrast injections are carefully controlled for volume, rate of injection and timing by ECG-gated power injection. (4) Images are processed by mask-mode subtraction rather than gated interval difference, because motion artifact has been considerably reduced by atrial pacing and precise ECG gating. (5) Both density and appearance time information is utilized in image analysis. These changes have been incorporated into our current clinical catheterization method.

This technique for measuring relative regional coronary blood flow is founded on other inflow videodensitometric techniques,[2,3] but significant differences do exist. First, relative flow ratios rather than absolute flow values are produced, eliminating the need for absolute density measurements. Rather than use the indicator-

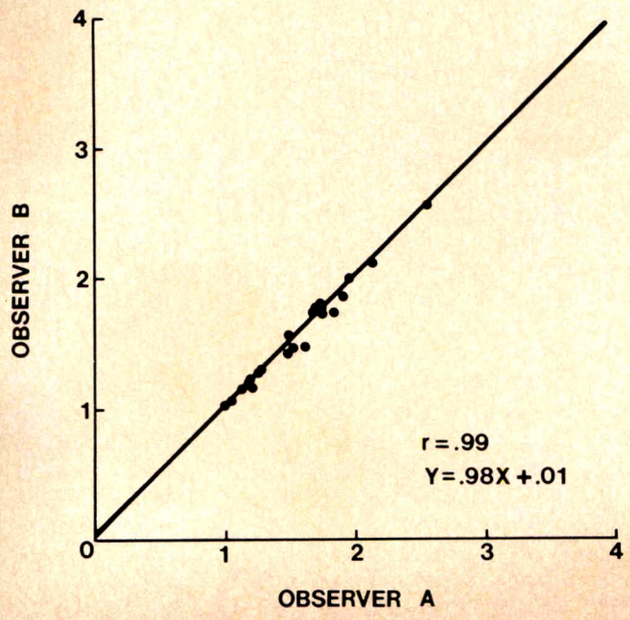

FIGURE 4. Interobserver variability. Observers A and B showed excellent agreement for appearance time ratios.

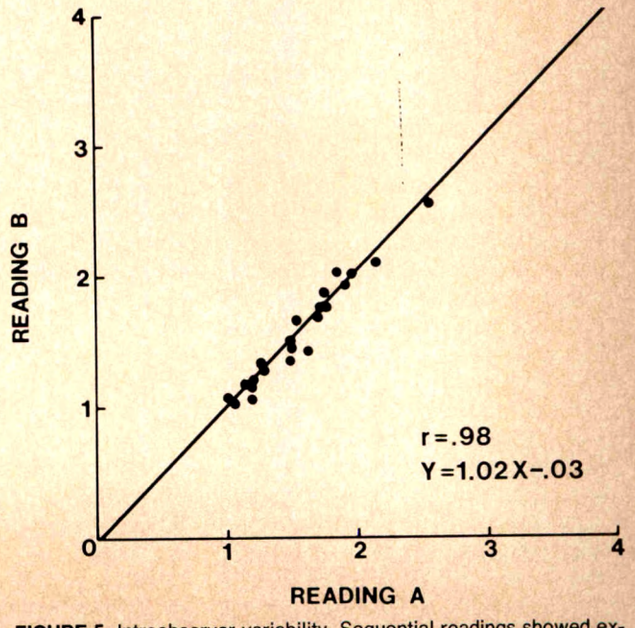

FIGURE 5. Intraobserver variability. Sequential readings showed excellent agreement for appearance time ratios.

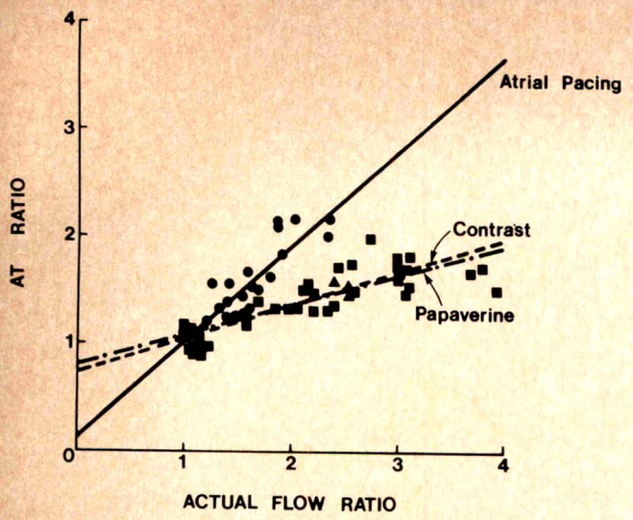

FIGURE 6. Comparison of appearance time (AT) ratios calculated for differing methods of inducing hyperemia. Actual flow ratios were calculated from coronary sinus flow measurements for atrial pacing and from electromagnetic flow measurements for both contrast and papaverine-induced hyperemia. Note the marked underestimation of actual flow ratios for both methods of pharmacologically induced hyperemia. The **circles** represent atrial pacing hyperemia; the **squares** represent contrast-induced hyperemia; the **triangles** represent papaverine-induced hyperemia.

dilution approach of Foerster et al,[6] which requires that a known or fixed amount of contrast be injected completely down the artery, we used a volumetric videodensitometric method. Second, these functional images can be generated within a few minutes of acquisition, allowing for repetition of studies with motion artifact. Third, this is the first method that uses myocardial regions of interest as suggested by Robb et al.[7] This allows the use of relatively large areas of interest (3,000 to 5,000 pixels), which can be placed in specific regional distributions at the discretion of the operator. Other techniques[2,3,6,8–10] require precise localization of small areas of interest over epicardial arteries and, in addition, require precise measurement of arterial diameter to obtain quantitative flow measurements.[2,3,9,10] The coronary anatomy in our images is used only as a guide to the placement of an appropriate myocardial area of interest. Although subject motion is the most important factor in CMAP quality, a small degree of misregistration does not appear to substantially affect the accuracy of flow ratio estimates. Fourth, precisely gated digital radiographic acquisition allows flow information to be generated using only 1 frame/cardiac cycle. Thus, radiation is reduced greatly compared with techniques that use 30 to 100 Hz acquisition.[2,3,6,8–10]

Several limitations should also be mentioned. Atrial pacing is necessary for accurate gating. The use of a power injector to deliver the contrast bolus is a complicating factor. However, we have not experienced any complications related to power injection in more than 200 patients. Other investigators[9–11] have also used power injection without complication. Finally, as with all digital subtraction techniques, patient motion can produce artifact.

Coronary blood flow was measured by EMF probe in this validation study. The observed mean maximal contrast-induced flow ratios (2.74, n = 13) are within the broad range of reported values determined by rotameter (2.14)[12] or EMF probe (3.7, 2.64).[13,14] EMF probes are dependent on close vessel probe contact. In all cases, our probes fit snugly and we observed no variation in the baseline (0 flow) determination between successive measurements. Blood flow measurements were made just before contrast medium injection, but the latter was not observed to have substantial effect on the flowmeter values during injection. We acquired images without removing the catheter from the coronary ostium and noted no impairment in coronary flow reserve. We observed prompt free reflux of contrast into the aorta on all injections, indicating that the catheter was not wedged and that the contrast flow rate was sufficient to achieve 100% contrast concentration within the artery. Other investigators also have found no differences between coronary flow measurements made with and those made without the catheter removed.[6,14–17]

This technique uses inflow (washin) transit-time analysis, the principle of which is described in equation 1.[2,3] In the original description of this technique,[1] the assumption was made that the volume of distribution remained constant. In that study, changes in coronary sinus blood flow were induced by atrial pacing and were inversely correlated with changes in digitally generated mean appearance times (r = 0.90). The slope of the regression equation was 0.79, suggesting that during flow increases induced by atrial pacing, the volume of distribution remained relatively constant. However, when contrast was used as a hyperemic stimulus for the present validation study, the volume of distribution did change during contrast-induced hyperemia. Figure 2 shows the underestimation of true contrast-induced hyperemic flow when appearance time alone was used to generate digital flow ratios. Despite a reasonable correlation (r = 0.78), the regression equation yielded a very low slope (0.29). Recruitment of capillaries,[18] capillary dilatation,[19,20] fluid shifts into the vascular compartment[21,22] and dilatation of epicardial arteries[23] have been observed during pharmacologically induced hyperemia. Actual measured total myocardial vascular volume also increase markedly after pharmacologic vasodilatation or hypoxia.[24–27] In these situations, where the distributional volume is increased, changes in coronary flow will be underestimated by changes in coronary flow velocity.[23] Because appearance time measures coronary flow velocity, it would be expected to underestimate flow after contrast-induced hyperemia (Fig. 2).

Würsten et al[28] showed that these volume changes can be measured directly by angiographic CD changes. Therefore, to correct the volume of distribution alterations, we used CD information. The CD/AT value (defined in equation 4) represents this corrected flow estimate. Because the absolute volume of distribution is not known, CD/AT values represent only relative and not absolute flow estimates. Figure 6 shows the relation between AT ratios and true flow ratios for several methods of inducing hyperemic flow. Atrial pacing

hyperemia is not underestimated by measurements of flow velocity alone, whereas both papaverine and contrast-induced hyperemic flow AT ratios show considerable underestimation of true flow changes. This substantiates our observation[1] that the intensity of myocardial blush on images obtained during contrast-induced hyperemia was much greater than that on images obtained during pacing-induced hyperemia.

Electrophysiologic and Anatomic Changes in the Atrioventricular Junction of Dogs After Direct-Current Shocks Through Tissue Fixation Catheters

MELVIN M. SCHEINMAN, MD, SAROJA BHARATI, MD, YIN-SHI WANG, MD, WILLIAM A. SHAPIRO, MD, and MAURICE LEV, MD

Barb-tipped fixation electrode catheters were inserted under fluoroscopic control in the region of the atrioventricular (AV) node in 6 dogs. A series of direct-current shocks (20 to 240 J) were delivered from the electrode catheter to a back plate. Serial electrophysiologic studies were performed before and 2 to 3 weeks after delivery of the shocks. In general, low-energy shocks—20 to 180 J—resulted in predominant damage to the approaches to the AV node, the AV node and common bundle, whereas larger shocks created diffuse damage involving the His bundle and bundle branches. Despite histologic damage to the AV junction, only minimal changes in AV conduction were observed. Thus, there is a large safety margin for AV conduction.

(Am J Cardiol 1985;55:194–198)

A technique for closed-chest catheter ablation of the atrioventricular (AV) junction has been recently described in dogs[1,2] and extended for clinical use.[3–5] This technique is limited because tachycardia control is achieved at the expense of pacemaker dependency. The objective of the present study was to assess the effects of electrical energy delivered through catheters fixed in the region of the AV node in order to create a model of impaired AV conduction without need for chronic pacing.

Methods

Six mongrel closed-chest dogs that weighed 25 to 35 kg were anesthetized with sodium pentothal and ventilated by a Harvard respirator. A standard no. 6 USCI quadripolar electrode catheter was positioned across the tricuspid valve for His bundle recordings. A separate electrode catheter was positioned against the high lateral right atrial wall for pacing. Either a modified USCI bipolar catheter with barbed tip or a Medtronic no. 6917 screw catheter was used. In 3 dogs, it was possible to cannulate the coronary sinus and the fixation catheter was inserted between catheters (Fig. 1) by means of biplane fluoroscopy. In 3 other dogs, the tissue fixation catheter was inserted just posterior and inferior to the site of the largest His deflection. Baseline AV conduction intervals were recorded, anterograde refractory periods were measured, and incremental atrial overdrive pacing (at 20-ms increments) was used to ascertain the minimal cycle length at which 1:1 AV conduction occurred. A plate lubricated with conduction gel was positioned behind the back between the scapulae. The distal electrode was used as a current source (cathode) and the back plate was used as the current sink (anode) from a Physio-Control defibrillator. This defibrillator was modified to deliver direct-current shocks in 20-J increments. The initial energy was 20 J and incremental shocks were delivered until second- or third-degree AV block was produced. The site of AV block was localized by His recordings. Return of 1:1 AV conduction occurred in all dogs within 35 minutes. The dogs were examined daily by a veterinarian with 2-minute surface electrocardiographic strips obtained 3 times per week. Studies of AV conduction were repeated at 2.5 weeks. Changes in the AV nodal refractory period could not be assessed in 4 dogs due to either achievement of atrial refractoriness or induction of rapid polymorphous unsustained atrial arrhythmias.

All dogs were killed after the repeat study for gross examination of the heart, coronary vessels and detailed examination of the cardiac conduction system.

Method of study of the conduction system: Blocks were taken from the sinoatrial node, AV node, bundle and bundle branches up to the moderator band. These blocks included the approaches to the sinoatrial and AV nodes. The blocks were serially sectioned. Every twentieth section was stained

alternatively with hematoxylin-eosin and Weigert-Van Gieson stains. Approximately 1,200 sections were examined for each dog.

Results

The electrophysiologic findings are summarized in Table I. The amount of energy required to acutely produce second- or third-degree AV block varied from 20 to 240 J. With low-energy shocks (20 to 180 J), acute

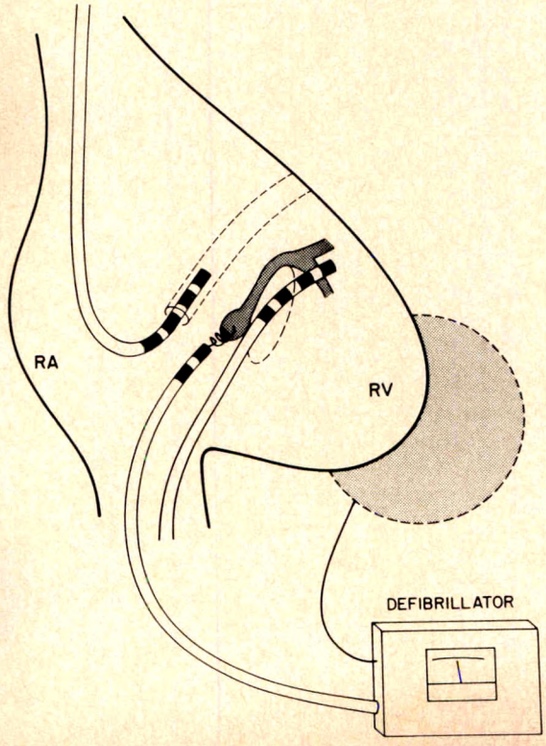

FIGURE 1. Placement of screw-in electrode in the vicinity of the atrioventricular node. RA = right atrium; RV = right ventricle.

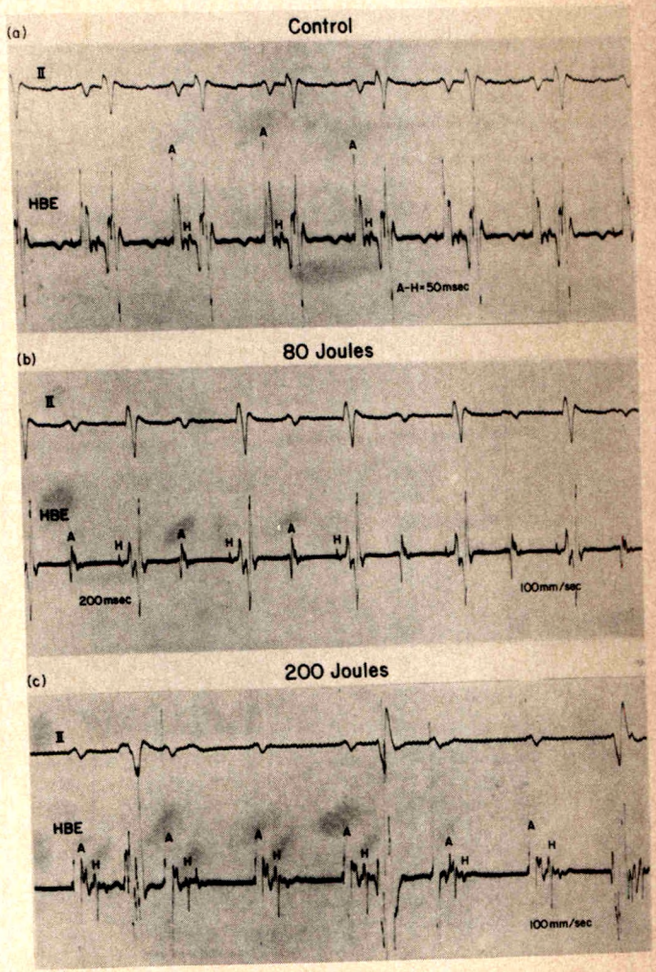

FIGURE 2. Simultaneous recordings of surface lead II and the His bundle electrogram (HBE) before (**a**) and after delivery of 80 J (**b**) and 200 J (**c**). After 80 J, first-degree AV block is localized to the level of the atrioventricular node as reflected by the marked lengthening of the AH interval. After delivery of a total of 200 J, complete infranodal block is apparent.

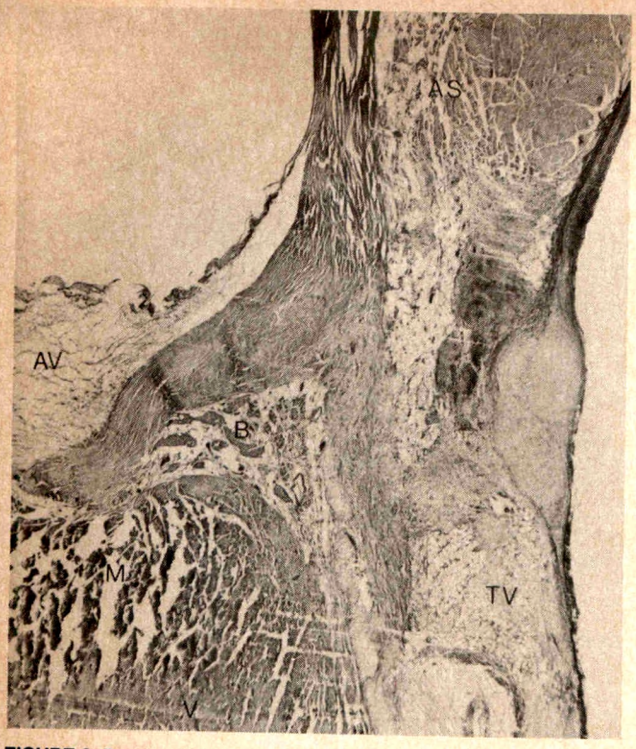

FIGURE 3. Bundle of His (B) in dog 1, showing dissolution of tissue and space formation. Also visible is degeneration of spongiosa of anulus of aortic valve (AV) and tricuspid valve (TV) and coagulative necrosis of some myocardial fibers (M) in summit of the ventricular septum (V). AS = atrial septum. Weigert-van Gieson stain; magnification × 30, reduced 27%.

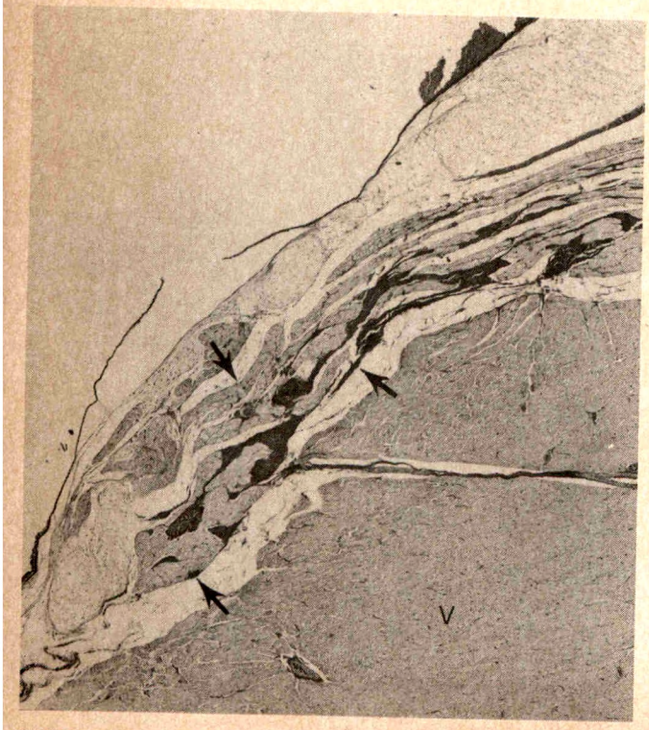

FIGURE 4. Fibrosis of beginning of left bundle in dog 4. **Arrows** point to left bundle. V = ventricular septum. Weigert-van Gieson stain; magnification × 45, reduced 23%.

AV block was always localized to the AV node. Higher-energy shocks (200 to 240 J) caused acute block both at the node and below the node. The sites of block immediately after shock were localized to the AV node in dogs 1 to 4, and were both AV nodal and infranodal in dogs 5 and 6. Physiologic infranodal block, because of AV nodal Wenckebach cycles, was not observed (Fig. 2). One-to-one AV conduction returned by 35 minutes in all dogs. Analysis of all follow-up electrocardiographic recordings showed 1:1 AV conduction with normal QRS width. Although a bundle branch block pattern was occasionally observed just after the shocks, none was apparent on the follow-up tracings.

There was no significant change in the baseline AV nodal (AH) or infranodal conduction (HQ) times before and 2 to 3 weeks after shock, but the minimal paced cycle lengths that produced 1:1 conduction increased significantly (from 205 ± 8 to 227 ± 21 ms, $p < 0.01$). In addition, in the 2 dogs who showed no change in this measurement, the AH interval was longer at the same paced cycle length. There was a significantly greater increase in the mean AH interval after shock (from 90 ± 10 to 126 ± 15 ms, $p < 0.01$) at the minimal atrial paced cycle length which resulted in 1:1 AV conduction. Changes in the AV nodal refractory period could be

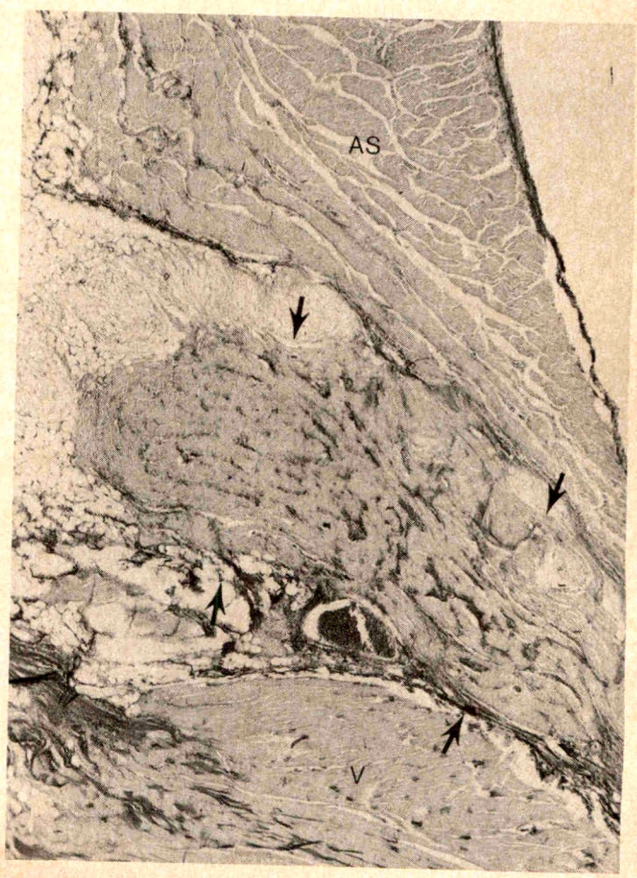

FIGURE 5. Atrioventricular node in dog 5, showing fibrosis (**arrows**). AS = atrial septum; V = ventricular septum. Weigert-van Gieson stain; magnification × 45, reduced 27%.

compared in 2 dogs, lengthening by 10 and 15 ms, respectively, after shock.

Atrial overdrive pacing failed to produce either increase in the HQ interval or infranodal conduction block. The effective refractory period of the His-Purkinje system was achieved in only dog 2, 2 weeks after shock. In all dogs, 1:1 AV conduction returned and remained stable over the 2- to 3-week observation period.

Gross examination of the heart: There was mild fibroelastosis seen in the AV node in dog 1. Marked thickening at the base of the septal leaflet of the tricuspid valve with focal fibrosis in the superior approaches to the AV node was present in dogs 2 to 6. The medial leaflet of the tricuspid was swollen in all. Otherwise, the hearts were normal at a gross level. The marked fibrosis observed in the region of the AV junction precluded assessment of anatomic location of the tissue-fixation catheters in relation to the AV node.

The amount of permanent injury produced in the approaches to the AV node, and the AV node in dogs 1 and 2 were mild and became somewhat more marked in the His bundle (Fig. 3) and bundle branches. In dog 3, damage was significant in the approaches to the AV node and the AV node itself, and became less in the His or common bundle and right bundle, but was severe in the left bundle with almost complete interruption of the beginning of the left bundle. In dog 4, the pathologic change was considerable in the approaches to the AV node, the AV node, and the His bundle and bundle branches (Fig. 4), but there was no interruption in continuity of structures. In dog 5, the injury to the AV node (Fig. 5) and His bundle (Fig. 6) were moderate, but marked in the bundle branches (Fig. 7). In dog 6, it was significant in the approaches to the AV node, the AV node itself, less in the His bundle and considerable in the bundle branches but without interruption of the bundle branches.

Discussion

After shocks were delivered through tissue fixation catheters, only minor changes in AV conduction were observed and only with atrial overdrive pacing. In general, dogs that received low-energy shocks (20 to 140 J) showed predominant damage to the AV node and common bundle. Those that received higher-energy shocks (180 to 240 J) showed significant damage of the

FIGURE 6. His bundle in dog 5, showing compression and an infiltration of mononuclear cells. Also seen is degeneration of the subendocardium and connective tissue (CT) on the left of the bundle and young connective tissue (Y) on the right of the bundle. **Arrows** point to AV bundle. FIGURE 7. Marked fibrosis of right bundle in dog 5. **Arrows** point to right bundle. B = AV bundle; V = ventricular septum. Weigert-van Gieson stain; magnification × 63, reduced 27%.

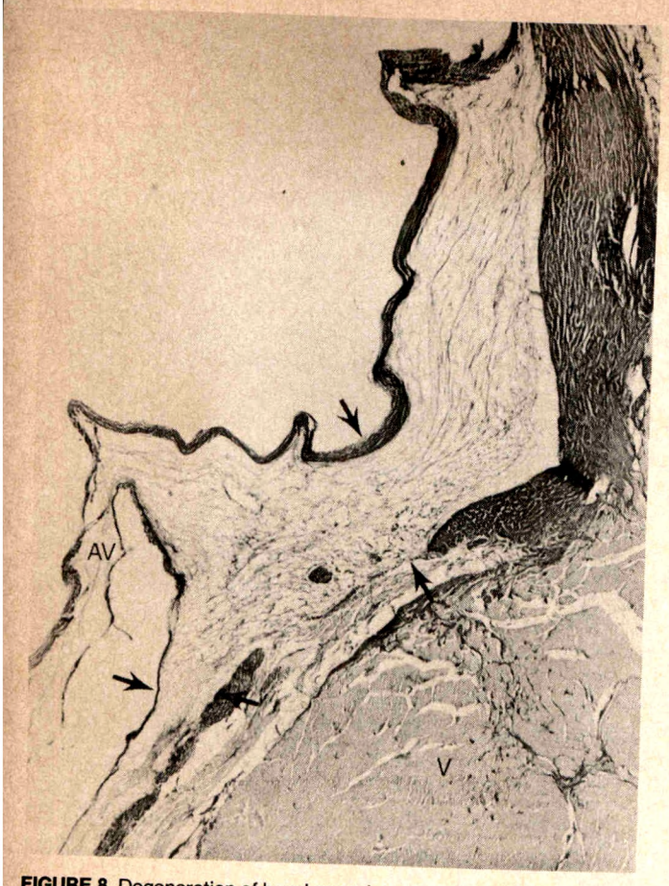

FIGURE 8. Degeneration of basal spongiosa or aortic valve (AV) in dog 2. **Arrows** point to basal spongiosa. V = ventricular septum. Weigert-van Gieson stain; magnification × 45, reduced 28%.

node, common bundle and bundle branches. Complete interruption of the conduction system was not observed. Other findings included degenerative changes in the central fibrous body and summit of the ventricular septum as well as changes in the spongiosa of the tricuspid and aortic valves (Fig. 8). No damage to the epicardial coronary vessels were observed.

Limitations: A potential limitation of this study is the possibility that different doses of sodium pentobarbital (longer duration of anesthesia for the first study) may have affected AV nodal conduction. In addition, the delivered shocks may have altered the autonomic supply to the AV junction and conceivably affected AV nodal conduction. Finally, although more severe histologic damage to the infranodal conduction system was observed in dogs that recieved larger amounts of electrical energy, it is not clear why the predominant electrophysiologic changes were localized to the AV node.

Significance of findings: Although the experiments were designed to deliver localized energy to the region of the AV node, tissue fixation catheters produced significant diffuse damage to multiple areas of the AV conduction system. We show the enormous safety margin of AV conduction, in that dogs with 50% or greater histologic destruction of part of the AV conduction system showed only small functional changes in AV conduction. Whether this degree of damage will allow arrhythmia control in patients with supraventricular tachycardia refractory to medical therapy remains unknown. This technique may allow treatment of these patients without production of complete AV block with permanent pacemaker dependency.

Mechanical "Cough" Cardiopulmonary Resuscitation During Cardiac Arrest in Dogs

JAMES T. NIEMANN, MD, JOHN P. ROSBOROUGH, PhD, ROBERT A. NISKANEN, MSEE, CLIF ALFERNESS, BSEE, and J. MICHAEL CRILEY, MD

Hemodynamic findings during ventricular fibrillation (VF) and closed-chest cardiopulmonary resuscitation (CPR) are similar to those described during VF and vigorous coughing. Interventions during CPR that mimic the physiologic events of coughing (high intrathoracic pressure and high intraabdominal pressure) improve perfusion during VF and CPR. An external circulatory assist apparatus was devised to emulate cough physiology, i.e., simultaneous pulsatile increases in intrathoracic pressure (pneumatic vest), intraabdominal pressure (abdominal binder) and airway pressure (high-pressure airway inflation). In this study, vest/binder CPR was compared with conventional CPR during 30 minutes of VF and artificial support in 18 randomized dogs. Defibrillation and long-term (more than 24 hours) survival were chosen as end points. During VF and artificial support, aortic and right atrial (RA) pressures, the instantaneous aortic-RA pressure difference (coronary perfusion pressure) and blood gas levels were measured. After 30 minutes of VF and administration of 1 mg of epinephrine, countershock was attempted. Systolic aortic and RA pressures, mean aortic-RA pressure difference and blood gas levels were not significantly different between dogs that were successfully resuscitated and those that were not. However, peak diastolic coronary perfusion pressure (peak diastolic aortic-RA pressure) for survivors averaged 23 ± 6 mm Hg, but only 6 ± 10 mm Hg for nonsurvivors ($p < 0.001$). A peak diastolic coronary perfusion pressure 16 mm Hg or greater had a positive and negative predictive value for a successful outcome of 1.00. Only 1 of 9 conventional CPR dogs survived 24 hours; 7 of 9 dogs supported with the vest/binder device were alive and neurologically normal at 24 hours ($p = 0.007$). Thus resuscitation techniques that exploit the CPR "thoracic pump" can sustain systemic perfusion during VF, and diastolic coronary perfusion pressure is a determinant of CPR/countershock outcome and is favorably manipulated by mechanical means.

(Am J Cardiol 1985;55:199–204)

Vigorous coughing during circulatory collapse produces arterial pressure pulses and cardiac output.[1,2] Hemodynamic findings during ventricular fibrillation (VF) and conventional closed-chest cardiopulmonary resuscitation (CPR) are similar to those described during cardiac arrest and so-called cough CPR.[3,4] In an animal model, single coughs, produced by electrical stimulation of the cervical vagosympathetic trunks, generate greater carotid arterial flow than CPR systoles.[5] Newer, experimental CPR techniques[6–8] have incorporated adaptations (abdominal binding with or without simultaneous chest compression and lung ventilation) that mimic the physiologic events of vigorous cough, i.e., pulsatile, simultaneous increase in intrathoracic and intraabdominal pressure of brief duration.

The potential use of cough CPR as an artificial circulatory support technique has been limited to selected settings.[1,2] Although capable of maintaining vital organ perfusion during circulatory collapse, the technique cannot be used for prolonged arrest because of fatigue. However, the use of conventional closed-chest CPR may also be limited during prolonged arrest. Several studies indicate that the absence of a substantial pressure difference between the aorta and right atrium during conventional CPR may preclude effective coronary perfusion and successful cardiac resuscitation.[9–11] In this investigation, CPR performed with a pneumatic device, designed to emulate the physiologic events of spontaneous cough, was studied and compared with

conventional CPR with respect to countershock outcome and long-term survival after prolonged VF.

Methods

Animal preparation: Eighteen mongrel dogs that weighed 16 to 30 kg were anesthetized with ketamine hydrochloride (10 mg/kg body weight intramuscularly). All dogs were then intubated and anesthesia was maintained with methoxyflurane. During instrumentation, the dogs were mechanically ventilated and heart rate and rhythm were monitored continuously with standard lead II. Transducer-tipped catheters (Millar Mikro-Tip®, size 7Fr with a side hole) were inserted into a femoral artery and vein using a sterile percutaneous sheath technique and advanced into the ascending thoracic aorta and right atrium. Catheter tip position was confirmed either fluoroscopically or by characteristic pressure tracings. Sterile catheters were calibrated in a 0.9% saline bath at 37°C before intravascular insertion. A bipolar pacing catheter was inserted percutaneously into a femoral vein and advanced until the distal electrode was in contact with right ventricular endocardium. Airway pressure was measured with a calibrated Statham P23ID transducer through a side hole in the endotracheal tube connector.

Control intravascular pressures were recorded over a 10-minute period and arterial blood was sampled from the ascending aorta during assisted ventilation with 100% oxygen. Minute ventilation was adjusted or intravenous sodium bicarbonate administered, if needed, to provide an arterial pH of 7.36 or more. Ventricular fibrillation was then induced by passing alternating current through the right heart catheter. Aortic and RA pressures were allowed to stabilize for 30 to 60 seconds before artificial circulatory support was initiated.

Experimental protocols: The dogs were unselected for body weight or chest configuration and were randomized to receive 1 of 2 techniques of artificial circulatory and ventilatory support during VF. Conventional CPR was performed in 9 dogs. Anteroposterior sternal depressions and positive pressure lung inflations with 100% oxygen were administered with a commercially available, cylinder-piston device (Thumper®, Michigan Instruments). The sternum of the supine dogs was depressed 2 to 3½ inches with piston force and depth of compression adjusted to produce an aortic systolic pressure at least 60 mm Hg. Sternal compression was performed at a rate of 60 compression cycles/min. Compression was maintained for 0.5 second (systole) and was followed by a relaxation phase (diastole) of equal duration. A positive pressure lung inflation with a tidal volume of 15 ml/kg was delivered every fifth diastole.

In 9 other dogs, artificial circulatory and ventilatory support was provided with an inflatable, 2-component pneumatic bladder system. The thorax was circumferentially enclosed in an adjustable, snug-fitting vest garment. The abdomen was bound with a circumferential binder that extended from the coastal margins to the midpelvis. The pneumatic bladders of the vest and binder were simultaneously inflated to pressures of 200 and 100 mm Hg, respectively, at a rate of 50 inflations/min. Pneumatic bladder inflation was maintained for 0.6 second (systole) and was followed by a deflation phase (diastole) of equal duration. The lungs were inflated synchronously with vest and binder inflation using a tidal volume of 15 ml/kg for each ventilation.

Artifical circulatory and ventilatory support using conventional CPR or vest/binder CPR was performed during a 30-minute period of VF. Systolic, diastolic and mean aortic and right atrial (RA) pressures were determined every 5 minutes. The instantaneous coronary perfusion pressure (aortic-RA pressure difference) was directly recorded using an electronic subtraction circuit, and systolic, diastolic and mean coronary perfusion pressures were similarly determined at 5-minute intervals. Arterial blood samples were taken from the ascending aorta 10, 20, 25 and 30 minutes after induction of VF and CPR and analyzed for PaO_2, $PaCO_2$ and pH. Sodium bicarbonate (1 mEq/kg) was administered as required to maintain arterial pH above 7.25 during CPR with either technique.

Twenty-five minutes after CPR had been initiated, 1 mg of epinephrine was administered to all dogs through a forelimb vein. Five minutes later, defibrillation was attempted using 100 J. In dogs that underwent conventional CPR, defibrillation was attempted with conventional paddles and conductive gel. In dogs that underwent vest and binder CPR, adhesive, pre-gelled electrodes were used to eliminate the delay in removing the vest before countershock.

If the first attempt to defibrillate at 100 J was successful, sodium bicarbonate was administered as needed to correct metabolic acidemia and an epinephrine drip (2.5 mg in 250 ml of 5% dextrose) was used as necessary to support arterial systolic pressure at a level of 80 mm Hg or greater. When arterial pressure had stabilized and pressors discontinued, intravascular catheters were removed, replaced in a 0.9% saline bath at 37°C, and recalibrated to check for drift. The endotracheal tube was removed when a cough reflex and spontaneous respirations were present, and the dog was observed over the ensuing 24 hours.

If the first defibrillation attempt at 100 J failed, a second shock at 100 J was delivered. If again unsuccessful, defibrillation was attempted up to 5 times at delivered energies of 200, 300 and 400 J. If VF persisted or if asystole, a pulseless idioventricular rhythm or electricomechanical dissociation resulted, CPR with the assigned technique was continued, arterial blood gases were analyzed at 5- to 10-minute intervals, and sodium bicarbonate, epinephrine, atropine and further defibrillation attempts were used according to current guidelines.[12] No dog received conventional antiarrhythmic drugs. If a cardiac rhythm productive of arterial pressure

pulses (with or without pressor support) had not been achieved within 30 mintues of the first attempt at defibrillation, resuscitation was considered to have failed and the experiment was terminated. Transducer-tipped catheters were recalibrated in a 0.9% saline bath at 37°C and drift was recorded.

Data analysis and statistical methods: Peak systolic and mean aortic and RA pressures were measured every 5 minutes using an on-line microcomputer. Mean pressures were derived by computer integration of the respective pressure traces during thoracic compression and relaxation. End-diastolic pressures were directly measured by the investigators. The instantaneous difference between ascending aortic and RA pressures was recorded on a separate channel using an electronic subtraction circuit. On-line computer analysis allowed computation of peak systolic and diastolic differences, as well as the mean difference, obtained by integration of the area of the pressure trace during CPR systole and diastole.

The unpaired Student *t* test (2-tailed) was used to test statistical differences between systolic, end-diastolic, and mean aortic and RA pressures, mean and peak diastolic coronary perfusion pressures, and PaO_2, $PaCO_2$ and pH in dogs that were resuscitated and in those that were not. Fisher's exact test was used to test the null hypothesis that the outcome (24-hour survival) of dogs that received conventional CPR was not different from that of dogs that underwent vest/binder CPR. A p value <0.05 was considered statistically significant.

Results

There was no significant difference in body weight between dogs that received conventional CPR (20 ± 2 kg) and those that received pneumatic circulatory support with the vest and binder apparatus (23 ± 4 kg). Control intravascular pressures and arterial PaO_2, $PaCO_2$ and pH were also similar (Table I). Pressure and blood gas differences between dogs that were subsequently resuscitated (group 1) and those that died (group 2) were not apparent during the control period (Table I).

Intravascular pressures measured at 5-minute intervals during artificial circulatory and ventilatory support are shown in Table II. During the relaxation phase (diastole) of conventional CPR, coronary perfusion pressure (aortic-RA pressure) was positive (aortic pressure greater than RA pressure) in 6 of the 9 dogs that received conventional CPR. A peak diastolic perfusion pressure was seen in these dogs within 200 ms of the onset of relaxation (Fig. 1) and averaged 8 ± 12 mm Hg. During chest compression, coronary perfusion pressure decreased to 0 mm Hg in most dogs. Occasionally, systolic aortic pressure exceeded RA pressure, or the reverse was seen, and a positive or negative perfusion gradient was recorded. This was most often encountered after 15 minutes of chest compression and was believed to be the result of direct cardiac or vascular compression facilitated by changes in thoracic compliance. Mean coronary perfusion pressure averaged only 3 ± 10 mm Hg.

During vest and binder CPR, peak airway pressure ranged from 100 to 120 mm Hg. Systolic and mean aortic and RA pressures were significantly greater than those measured during conventional CPR. Coronary perfusion pressure fluctuations were similar to those seen during conventional CPR (Fig. 2). However, diastolic coronary perfusion pressure was positive in all dogs. A peak diastolic perfusion pressure was seen

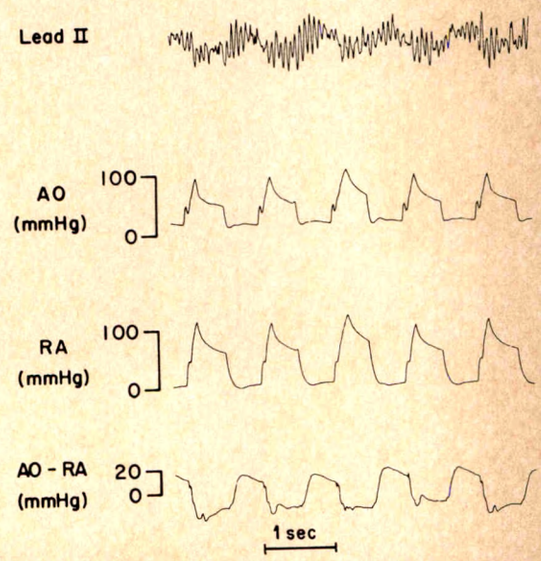

FIGURE 1. Intravascular pressures during ventricular fibrillation and conventional cardiopulmonary resuscitation. Ascending aortic (AO), right atrial (RA) and coronary perfusion (AO-RA) pressures after 25 minutes of ventricular fibrillation and conventional cardiopulmonary resuscitation. A positive pressure-lung inflation was given during the relaxation phase following the second compression in the depicted sequence. The greatest aortic minus right atrial pressure difference occurs during the relaxation phase.

within 300 ms of the onset of relaxation and averaged 21 ± 7 mm Hg ($p < 0.02$ vs conventional CPR) in these dogs during the 30-minute period of VF and artificial circulatory support. Mean coronary perfusion pressure averaged only 8 ± 5 mm Hg and was not significantly different from that measured during conventional CPR.

Nine of the 18 dogs (group 1) were successfully resuscitated after 1 or more countershocks. The cumulative stored energy dose required for successful defibrillation as 738 ± 1,061 J and the average number of defibrillation attempts was 5 ± 6 per dog. The peak current required for defibrillation averaged 27 ± 12 A in the 4 dogs in which it was measured. Four of the group 1 dogs had a peak diastolic coronary perfusion pressure of 25 mm Hg or greater during the 30-minute period of VF and artificial circulatory support. For these dogs, average cumulative energy dose and number of defibrillation attempts were 485 ± 267 J and 3 ± 1, respectively. Seven of the eight 24-hour survivors received vest/binder CPR.

Nine dogs (group 2) were not successfully resuscitated. Only 1 of these dogs had persistent VF after an additional 30 minutes of artificial circulatory support, repeated defibrillation attempts or conventional pharmacologic therapy (excluding antiarrhythmic drugs) for encountered rhythm disturbances. One dog treated with conventional CPR died of hemorrhagic shock 2 hours after successful cardiac resuscitation. The cardiac rhythm most frequently recorded before termination of the experiment in the remaining group 2 dogs was a pulseless idioventricular rhythm (agonal rhythm) (5 dogs). Eight of the group 2 dogs received conventional CPR during VF.

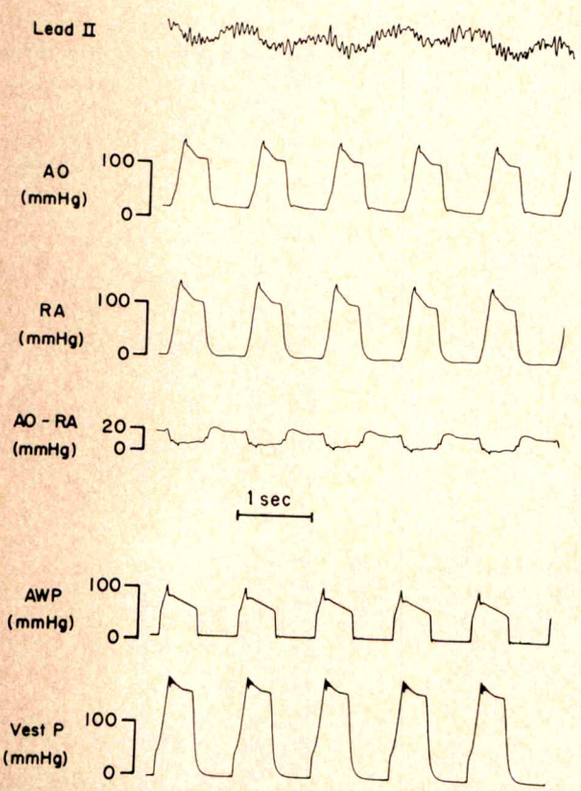

FIGURE 2. Intravascular pressures during ventricular fibrillation and vest and binder circulatory support. Ascending aortic (AO), right atrial (RA) and coronary perfusion (AO-RA) pressures after 25 minutes of ventricular fibrillation and vest/binder cardiopulmonary resuscitation (CPR). Airway pressure (AWP) and vest inflation pressure (Vest P) were also recorded. The vest, abdominal binder and airway were simultaneously inflated during each CPR "systole." The greatest aortic minus right atrial pressure difference is seen after rapid deflation of vest, binder and airway (CPR "diastole").

Hemodynamic and blood gas values for survivors and nonsurvivors are listed in Tables II and III. Successfully resuscitated dogs had significantly greater mean and end-diastolic aortic pressures and peak diastolic coronary perfusion gradients. The integrated mean coronary perfusion pressure was not significantly different between groups. Peak diastolic coronary perfusion pressure measured at 5-minute intervals for the groups are shown in Figure 3. Arterial blood gases were not significantly different between groups.

All successfully defibrillated dogs, except 1, were ambulatory and self-feeding within 24 hours of the experiment. The mean neurologic deficit score for the group was 0.[13] The 1 exception was a dog that received conventional CPR and that died from hemorrhagic shock 2 hours after successful cardiac resuscitation because of multiple liver lacerations. Although successfully defibrillated, resuscitation was considered to have failed in the analysis of the 24-hour outcome.

Only 1 of 9 dogs that underwent conventional CPR during the 30-minute period of VF was successfully defibrillated and survived for 24 hours. Seven of 9 dogs that received artificial circulatory support with the pneumatic vest and binder were defibrillated and survived 24 hours. The survival rate was significantly greater ($p = 0.007$, Fisher's exact test) for dogs that received vest/binder CPR.

Discussion

Artificial coughs produced by the pneumatic thoracic vest and abdominal binder mechanical device resulted in pulsatile systolic intravascular and airway pressure fluctuations of comparable magnitude. Parallel changes in intravascular and intrathoracic/airway pressures have been reported during closed-chest CPR.[3,4] However, mechanical cough CPR arterial pressures were greater than those seen during cardiac arrest and spontaneous cough in patients[1,2] or the electrically stimulated coughs in experimental animals,[5] and were maintained for 30 minutes. In addition, mechanical cough CPR produced greater arterial pressures than those usually reported during circulatory support with simultaneous chest compression and lung ventilation.[6–8]

Long-term survival was significantly different between dogs that received vest/binder circulatory support (7 of 9) and those that received conventional CPR (1 of 9). Successful cardiac resuscitation after prolonged arrest was largely dependent on the magnitude of the CPR peak diastolic aortic-RA pressure difference. A peak diastolic coronary perfusion pressure of 16 mm Hg or greater had a positive predictive value of 1.00 and a negative predictive value of 1.00 for countershock outcome. Dogs with peak diastolic coronary pressures of

more than 25 mm Hg required fewer countershocks and less energy for defibrillation than those with perfusion pressures of less than 25 mm Hg.

Our coronary perfusion pressure findings in the intact animal model are in close agreement with, and are supported by, in vitro studies of perfusion pressure requirements of the in vitro fibrillating heart. The fibrillating heart, although incapable of generating systemic perfusion, requires some minimal coronary flow to meet metabolic requirements and, at the same time, may impede coronary perfusion due to intramyocardial compressive forces.[14,15] In the setting of VF and CPR, intrinsic coronary vascular smooth muscle tone is probably at a minimum because of local vasoregulatory responses initiated by myocardial ischemia,[16–18] and intravascular impedance in a nonobstructed coronary vascular bed will be minimal. The in vivo fibrillating canine heart should thus approximate the in vitro fully vasodilated fibrillating heart. If so, resistance to flow will be primarily dependent on the vigor of myocardial contractions (extravascular compressive forces) during VF, and coronary blood flow will be largely determined by the aortic minus RA pressure difference.

In the in vitro model, myocardial perfusion ceases when the aortic-RA gradient falls below 15 to 18 mm Hg.[14,15] In this study, only 1 dog with a peak diastolic perfusion gradient of less than 18 mm Hg, averaged at 5-minute intervals during a 30-minute period of VF and artificial circulatory support, was defibrillated and alive 24 hours later. This dog received conventional CPR and the peak diastolic gradient was 16 mm Hg. No dog with a time-averaged peak diastolic coronary pressure of less than 16 mm Hg was successfully resuscitated.

We measured coronary perfusion pressure rather than coronary flow or myocardial perfusion because (1) electromagnetic flow may be influenced by movement artifacts and the low-flow state that characterizes closed-chest CPR; (2) the radio-labeled microsphere technique may not allow a reliable estimation of myocardial perfusion during CPR if restoration of normal cardiocirculatory function precedes termination of the experiment. A variable number of micropsheres are retained in the left heart blood pool after injection during CPR.[7,8] Redistribution of this pool after restoration of circulation could effect data interpretation; and (3) measurements of coronary flow during CPR in human subjects are not feasible, whereas measurements of aortic and RA pressures are. From a practical viewpoint, successful cardiac resuscitation is the goal of CPR. We attempted to correlate this goal with a quantitative measure which may be obtained in the clinical population. Independent studies by Luce et al,[19] using radiolabeled microspheres, demonstrated a significant correlation (r = 0.66) between peak diastolic coronary perfusion pressure and total myocardial flow. These investigators also reported that myocardial flow during vest/binder artificial circulatory support exceeds that of conventional CPR in the canine model.[7]

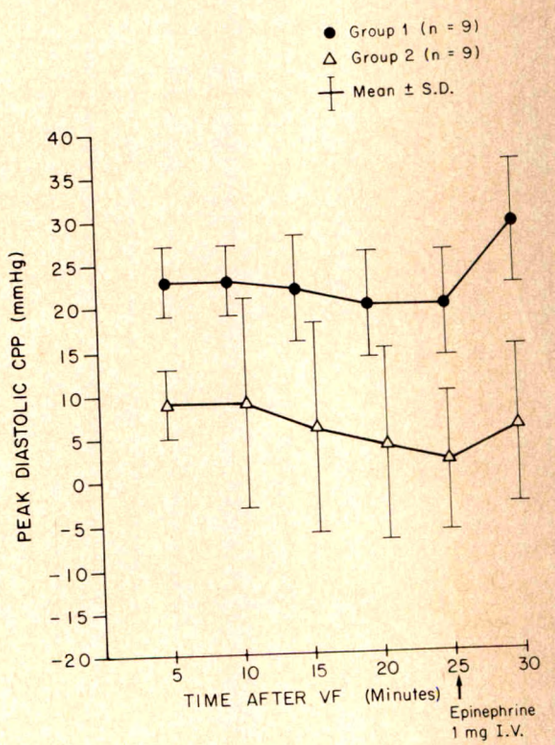

FIGURE 3. Coronary perfusion pressure (CPP) during prolonged cardiopulmonary resuscitation. Diastolic CPPs measured at 5-minute intervals during ventricular fibrillation (VF) and artificial circulatory support are shown. Data points have been slightly offset on the time scale to allow demonstration of standard deviations (S.D.). Epinephrine was given at 25 minutes. Diastolic CPP for successfully resuscitated dogs (group 1) averaged over the 30-minute period was 23 ± 6 mm Hg and was significantly greater ($p < 0.001$) than that measured in dogs that were not successfully defibrillated (group 2, 6 ± 10 mm Hg).

Epinephrine increased coronary perfusion pressure in both resuscitated and nonresuscitated dogs (Fig. 3). Previous investigations have shown that epinephrine increased diastolic aortic pressure and inferred that coronary perfusion pressure was improved.[20–22] However, the perfusion gradient was not measured. The present study supports and confirms this contention by direct measurement of the coronary perfusion gradient. In addition, the reported aortic diastolic pressures associated with successful resuscitation (23 ± 6 mm Hg) are considerably below previously reported values (30 to 40 mm Hg or greater).[11,20–22]

Almost all victims of sudden cardiac death have obstructive atherosclerotic coronary arterial disease.[24,25] Because of this, larger coronary perfusion pressures, greater than those reported in this canine study, may be required during CPR to sustain the metabolic requirements of the fibrillating human heart. Further studies assessing the magnitude of the coronary perfusion gradient and coronary flow during CPR and means by which they may be improved, either mechanically or pharmacologically, are indicated. Resuscitation techniques that exploit the thoracic pump mechanism for systemic perfusion during VF and artificial circulatory support are capable of sustaining vital organ perfusion during cardiac arrest in the most frequently studied model.

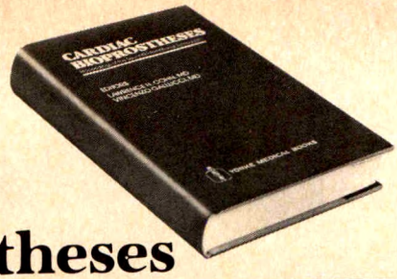
The most up-to-date presentation of the latest data on the entire range of clinical, bioengineering, pathology, and long-range follow-up issues on cardiac tissue valves.



Cardiac Bioprostheses

Proceedings of the Second International Symposium Rome, Italy, May 17-19, 1982

edited by Lawrence H. Cohn, MD, and Vincenzo Gallucci, MD
ISBN 0-914316-34-6, 609 pp., illus., Nov. 1982., $69.00

An international program committee organized this symposium on a strictly competitive abstract basis. It was held less than six months ago. One-hundred-eighty abstracts were submitted and 45 in 8 categories were accepted. Virtually every major cardiovascular center in the world that has any meaningful experience with cardiac bioprosthetic valves was represented. Nowhere will you find between two covers as much *current* information on the field of cardiac valves.

Almost 20 years have gone by since the first reports of homograft valve replacement by Drs. Donald Ross and Brian Barratt-Boyes and almost 10 years since the first reports began to appear about commercially available, quality-controlled porcine bioprosthetic and bovine pericardial valves. This book brings you completely up-to-date on what has happened since and what is happening *today*.

If your interests include the clinical, pathological and bioengineering aspects of cardiac bioprostheses then this book is a *must buy!* It should not be missing from your own professional library.

Who are the editors?

Lawrence H. Cohn, MD, is Professor of Surgery, Harvard Medical School, and Cardiothoracic Surgeon, Brigham and Womens' Hospital. He is the author of *Modern Techniques in Surgery* and co-author of the new annual, *Cardiology*, now available in its second issue, *Cardiology 1982*.

Vincenzo Gallucci, MD, is Professor of Cardiovascular Surgery, Departments of Cardiovascular Surgery and Cardiology, University of Padova Medical School, Padova, Italy.

International Symposium on Ischaemic Heart Disease

Organized by the Ischaemic Heart Disease Group of the Spanish Heart Society
Granada, Spain, April 11-13, 1985

Round Table Discussions

- Pharmacology of calcium antagonists
- Medical treatment of effort angina: Calcium antagonists, beta blockers
- Sudden death during the first year after myocardial infarction
- Platelet inhibition in coronary artery disease
- Fibrinolysis in ischaemic heart disease: A critical review
- Percutaneous transluminal coronary angioplasty: Eight years' experience

Lectures

- Risk assessment using noninvasive techniques following acute myocardial infarction
- Advances and developments in the treatment of patients with coronary artery disease
- Sudden death: The pathologist's point of view
- The Coronary Care Unit of the 1990's

The symposium will include workshops on PTCA, Fibrinolysis, Electrophysiology, Conducting Clinical Trials in the CCU.
Official languages: English and Spanish; simultaneous translation will be provided.

A148

ALDOMET (Methyldopa | MSD) tablets do not

TABLETS: 500 mg, 250 mg, and 125 mg

While the presence of sodium metabisulfite is probably important in a limited number of patients, it could be a factor in deciding whether to allow substitution for a prescription of ALDOMET®.

Although Tablets ALDOMET® do not contain any sulfite preservatives, as the Prescribing Information indicates, Oral Suspension ALDOMET® (Methyldopa, MSD) and Injection ALDOMET® Ester HCl (Methyldopate HCl, MSD) do contain sodium bisulfite as a preservative.

The use of any of these products is contraindicated in hypersensitive patients, in active hepatic disease, or if previous methyldopa therapy has been associated with liver disorders.

For a Brief Summary of Prescribing Information, please see following page.

MSD
MERCK SHARP & DOHME

A149

ALDOMET® (METHYLDOPA|MSD)

ALDOMET® Ester HCl (METHYLDOPATE HCl|MSD)

Tablets, containing 125, 250, or 500 mg methyldopa. Oral Suspension, containing 250 mg methyldopa per 5 ml and alcohol 1% with benzoic acid 0.1% and sodium bisulfite 0.2% added as preservatives. Injection for intravenous use, containing per 5 ml: methyldopate hydrochloride 250.0 mg; inactive ingredients—citric acid anhydrous 25.0 mg, disodium edetate 2.5 mg, monothioglycerol 10.0 mg, sodium hydroxide to adjust pH, and methylparaben 7.5 mg, propylparaben 1.0 mg, and sodium bisulfite 16.0 mg added as preservatives.

Contraindications: Active hepatic disease, such as acute hepatitis and active cirrhosis; if previous methyldopa therapy has been associated with liver disorders (see Warnings); hypersensitivity.

Warnings: It is important to recognize that a positive Coombs test, hemolytic anemia, and liver disorders may occur with methyldopa therapy. The rare occurrences of hemolytic anemia or liver disorders could lead to potentially fatal complfications unless properly recognized and managed. Read this section carefully to understand these reactions. With prolonged methyldopa therapy, 10% to 20% of patients develop a positive direct Coombs test, usually between 6 and 12 months of therapy. Lowest incidence is at daily dosage of 1 g or less. This on rare occasions may be associated with hemolytic anemia, which could lead to potentially fatal complications. One cannot predict which patients with a positive direct Coombs test may develop hemolytic anemia. Prior existence or development of a positive direct Coombs test is not in itself a contraindication to use of methyldopa. If a positive Coombs test develops during methyldopa therapy, determine whether hemolytic anemia exists and whether the positive Coombs test may be a problem. For example, in addition to a positive direct Coombs test there is less often a positive indirect Coombs test which may interfere with cross matching of blood. At the start of methyldopa therapy, it is desirable to do a blood count (hematocrit, hemoglobin, or red cell count) for a baseline or to establish whether there is anemia. Periodic blood counts should be done during therapy to detect hemolytic anemia. It may be useful to do a direct Coombs test before therapy and at 6 and 12 months after the start of therapy. If Coombs-positive hemolytic anemia occurs, the cause may be methyldopa and the drug should be discontinued. Usually the anemia remits promptly. If not, corticosteroids may be given and other causes of anemia should be considered. If the hemolytic anemia is related to methyldopa, the drug should not be reinstituted. When methyldopa causes Coombs positivity alone or with hemolytic anemia, the red cell is usually coated with gamma globulin of the IgG (gamma G) class only. The positive Coombs test may not revert to normal until weeks to months after methyldopa is stopped.

Should the need for transfusion arise in a patient receiving methyldopa, both a direct and an indirect Coombs test should be performed on his blood. In the absence of hemolytic anemia, usually only the direct Coombs test will be positive. A positive direct Coombs test alone will not interfere with typing or cross matching. If the indirect Coombs test is also positive, problems may arise in the major cross match and the assistance of a hematologist or transfusion expert will be needed.

Fever has occurred within first 3 weeks of therapy, occasionally with eosinophilia or abnormalities in liver function tests, such as serum alkaline phosphatase, serum transaminases (SGOT, SGPT), bilirubin, cephalin cholesterol flocculation, prothrombin time, and bromsulphalein retention. Jaundice, with or without fever, may occur, with onset usually in the first 2 to 3 months of therapy. In some patients the findings are consistent with those of cholestasis. Rarely fatal hepatic necrosis has been reported. These hepatic changes may represent hypersensitivity reactions; periodic determination of hepatic function should be done particularly during the first 6 to 12 weeks of therapy or whenever an unexplained fever occurs. If fever, abnormalities in liver function tests or jaundice appear, stop therapy with methyldopa. If caused by methyldopa, the temperature and abnormalities in liver function characteristically have reverted to normal when the drug was discontinued. Methyldopa should not be reinstituted in such patients. Rarely, a reversible reduction of the white blood cell count with primary effect on granulocytes has been seen. Reversible thrombocytopenia has occurred rarely. When used with other antihypertensive drugs, potentiation of antihypertensive effect may occur. Patients should be followed carefully to detect side reactions or unusual manifestations of drug idiosyncrasy.

Pregnancy and Nursing: Use of any drug in women who are or may become pregnant or intend to nurse requires that anticipated benefits be weighed against possible risks; possibility of fetal injury or injury to a nursing infant cannot be excluded. Methyldopa crosses the placental barrier, appears in cord blood, and appears in breast milk.

Precautions: Should be used with caution in patients with history of previous liver disease or dysfunction (see Warnings). May interfere with measurement of: urinary uric acid by the phosphotungstate method, serum creatinine by the alkaline picrate method, and SGOT by colorimetric methods. A paradoxical pressor response has been reported with intravenous use. Since methyldopa causes fluorescence in urine samples at the same wavelengths as catecholamines, falsely high levels of urinary catecholamines may be reported. This will interfere with the diagnosis of pheochromocytoma. It is important to recognize this phenomenon before a patient with a possible pheochromocytoma is subjected to surgery. Methyldopa is not recommended for patients with pheochromocytoma. Urine exposed to air after voiding may darken because of breakdown of methyldopa or its metabolites.

Stop drug if involuntary choreoathetotic movements occur in patients with severe bilateral cerebrovascular disease. Patients may require reduced doses of anesthetics; hypotension occurring during anesthesia usually can be controlled with vasopressors. Hypertension has recurred after dialysis in patients on methyldopa because the drug is removed by this procedure.

Adverse Reactions: *Nervous System/Psychiatric:* Sedation, headache, asthenia or weakness, usually early and transient; dizziness, lightheadedness, symptoms of cerebrovascular insufficiency, paresthesias, parkinsonism, Bell's palsy, decreased mental acuity, involuntary choreoathetotic movements; psychic disturbances, including nightmares and reversible mild psychoses or depression. *Cardiovascular:* Bradycardia, prolonged carotid sinus hypersensitivity, aggravation of angina pectoris. Paradoxical pressor response with intravenous use. Orthostatic hypotension (decrease daily dosage). Edema (and weight gain) usually relieved by use of a diuretic. (Discontinue methyldopa if edema progresses or signs of heart failure appear.) *Digestive:* Nausea, vomiting, distention, constipation, flatus, diarrhea, colitis, mild dryness of mouth, sore or "black" tongue, pancreatitis, sialadenitis. *Hepatic:* Abnormal liver function tests, jaundice, liver disorders. *Hematologic:* Positive Coombs test, hemolytic anemia. Bone marrow depression, leukopenia, granulocytopenia, thrombocytopenia. Positive tests for antinuclear antibody, LE cells, and rheumatoid factor. *Allergic:* Drug-related fever, lupus-like syndrome, myocarditis, pericarditis. *Skin:* Rash as in eczema or lichenoid eruption; toxic epidermal necrolysis. *Respiratory:* Nasal stuffiness. *Metabolic:* Rise in BUN. *Urogenital:* Breast enlargement, gynecomastia, lactation, amenorrhea, impotence, decreased libido. *Endocrine:* Hyperprolactinemia. *Musculoskeletal:* Mild arthralgia, with or without joint swelling; myalgia.

Note: Initial adult oral dosage should be limited to 500 mg daily in divided doses when given with antihypertensives other than thiazides. Tolerance may occur, usually between second and third months of therapy; increased dosage or adding a diuretic frequently restores effective control. Patients with impaired renal function may respond to smaller doses. Syncope in older patients may be related to increased sensitivity and advanced arteriosclerotic vascular disease; this may be avoided by lower doses.

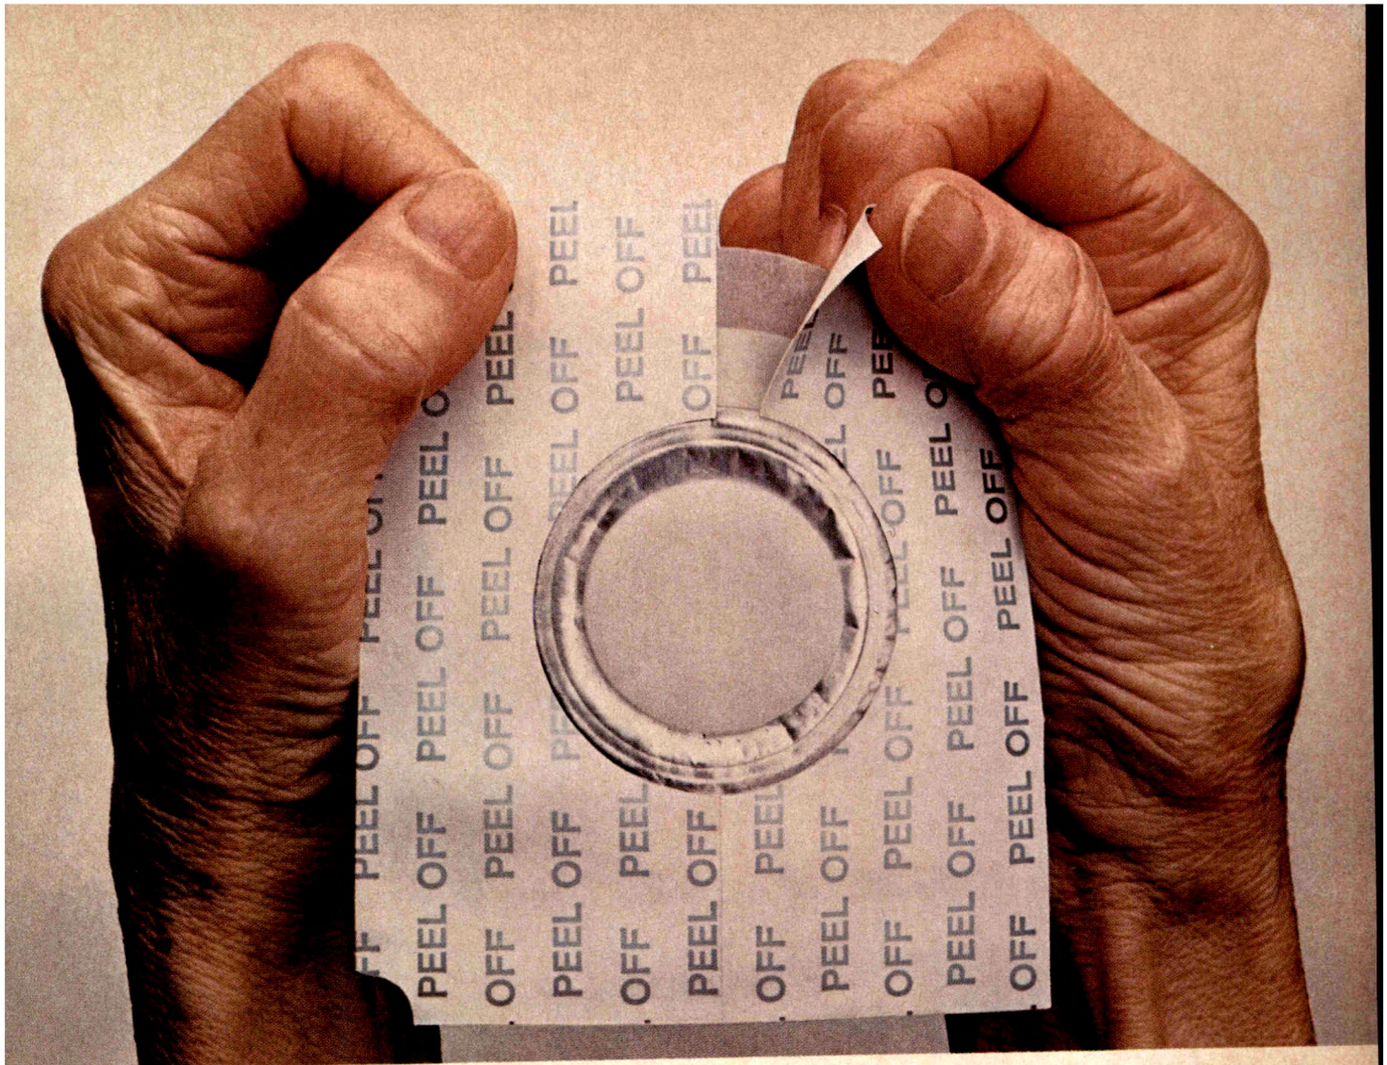
GERIATRICPROOF.



GERIATRIC PROVEN.

For elderly patients with angina,* the transdermal nitroglycerin patch on the left can be as difficult to open as a childproof cap.

Nitro-Dur is easier to open, easier to apply. Its size is comfortable to handle. Its backing is easy to peel off from any corner. And its application is simple—no continual pressure is needed. Nitro-Dur was designed to fit comfortably into the lives of angina patients—particularly the elderly.

No wonder it has won a place so close to so many hearts.

Symptoms of hypotension may be due to overdosage. If hypotension occurs, the dosage should be reduced. In terminating treatment, the dosage must be gradually reduced over a 4- to 6-week period.

*All transdermal nitroglycerin products are being marketed pending final evaluation of effectiveness by the FDA.

Nitro-Dur®
(nitroglycerin)
Transdermal Infusion System

Practical not pretty.

See next page for brief summary of prescribing information.

Nitro-Dur
(nitroglycerin)
Transdermal Infusion System

DESCRIPTION: The Nitro-Dur Transdermal Infusion System contains nitroglycerin in a gel-like matrix composed of glycerin, water (purified), lactose, polyvinyl alcohol, povidone and sodium citrate to provide a continuous source of the active ingredient. Nitro-Dur is available in dosage sizes 5cm², 10cm², 15cm² and 20cm², containing 26 mg, 51 mg, 77 mg and 104 mg of nitroglycerin, respectively, thereby providing a range of dosing levels of nitroglycerin. Each unit is sealed in a polyester-foil-polyethylene laminate. The bandage portion consists of a medical grade non-woven, heat sealable, microporous tape.

CLINICAL PHARMACOLOGY: When the Nitro-Dur system is applied to the skin, nitroglycerin is absorbed continuously through the skin into the systemic circulation. This results in active drug reaching the target organs (heart, extremities) before deactivation by the liver. Nitroglycerin is a smooth muscle relaxant with vascular effects manifested predominantly by venous dilation and pooling. The major beneficial effect of nitroglycerin in angina pectoris is a reduction in myocardial oxygen consumption secondary to vascular smooth muscle relaxation with resultant reduction in cardiac preload and afterload. In recent years there has been an increasing recognition of a direct vasodilator effect of nitroglycerin on the coronary vessels.

In bioavailability studies using healthy volunteers,[1] transdermal absorption of nitroglycerin from Nitro-Dur achieved steady state venous plasma levels, and maintained these levels for 24 hours. Detectable plasma levels were attained within 30 minutes after application of the system, and were still detectable 30 minutes after removal of the system. Precise definition of "therapeutic plasma level" is not known at this time.

INDICATIONS AND USAGE: This drug product has been conditionally approved by the FDA for the prevention and treatment of angina pectoris due to coronary artery disease. The conditional approval reflects a determination that the drug may be marketed while further investigation of its effectiveness is undertaken. A final evaluation of the effectiveness of the product will be announced by the FDA.

CONTRAINDICATIONS: Intolerance of organic nitrate drugs, marked anemia, increased intraocular pressure or increased intracranial pressure.

WARNINGS: The Nitro-Dur system should be used under careful clinical and/or hemodynamic monitoring in patients with acute myocardial infarction or congestive heart failure.

In terminating treatment of angina patients, both the dosage and frequency of application must be gradually reduced over a period of 4 to 6 weeks in order to prevent sudden withdrawal reactions, which are characteristic of all vasodilators in the nitroglycerin class.

Safe use in pregnancy has not been established relative to possible adverse effect on fetal development, but neither have adverse effects on fetal development been established. Therefore, use of nitroglycerin in pregnant women should be balanced against the risk of uncontrolled angina pectoris.

PRECAUTIONS: Symptoms of hypotension, such as faintness, weakness or dizziness, particularly orthostatic hypotension, may be due to overdosage. If during the course of treatment these symptoms occur, the dosage should be reduced or use of the product discontinued.

Nitro-Dur is not intended for use in the treatment of acute anginal attacks. For this purpose, occasional use of sublingual nitroglycerin may be necessary.

ADVERSE REACTIONS: Transient headache is the most common side effect, especially when higher doses of the drug are administered. Headaches should be treated with mild analgesics while continuing Nitro-Dur therapy. If headache persists, the Nitro-Dur dosage should be reduced.

Adverse reactions reported less frequently include hypotension, increased heart rate, faintness, flushing, dizziness, nausea, vomiting, and dermatitis. Except for dermatitis, these symptoms are attributed to the pharmacologic effects of nitroglycerin. However, they may be symptoms of overdosage. When they persist, the Nitro-Dur dosage should be reduced or use of the product discontinued.

HOW SUPPLIED: Nitro-Dur Transdermal Infusion System, 5cm², 10cm², 15cm² and 20cm², is available in unit dose packages of 28 and hospital packs of 100.

CAUTION: Federal law prohibits dispensing without prescription.

PATIENT INSTRUCTIONS FOR APPLICATION: Patient instructions are furnished with each unit dose package.

For complete prescribing information, please see package insert.

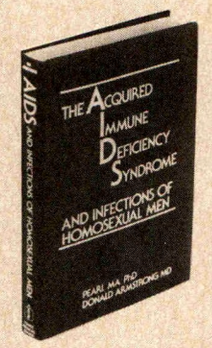
AIDS
An important new book on today's most virulent epidemic



From the Publishers of The American Journal of Medicine, The American Journal of Surgery, and Cutis

Acquire Immune Deficiency Syndrome (AIDS) and Infections of Homosexual Men

edited by **Pearl Ma, PhD,** and **Donald Armstrong, MD** with a foreword by **David J. Sencer, MD,** *Commissioner of Health, New York City; formerly Director, Centers for Disease Control, Public Health Service, U.S. Department of Health and Human Services*
0-914316-38-9, 442 pages, illus., 1984, $39.50

The first scientific presentation to review all the facts in full

AIDS has become one of the most publicized diseases in modern times. It has produced fear and confusion in the general public and presented a formidable challenge to the medical community. Physicians and scientists have begun work on managing this epidemic, disease control centers continue to search for answers, and the federal government has declared AIDS the number one health priority of the nation. Understanding this disease demands cooperation between many different medical specialties, and papers on this subject have been published in many diverse journals not regularly read by individual specialists. Now, for the first time, two highly distinguished medical experts, Drs. Pearl Ma and Donald Armstrong, have coordinated in one easily accessible volume the complete range of interdisciplinary approaches to this complex disease, with contributions by the most eminent researchers and physicians in disease control and hospital teaching centers throughout the country. Comprehensive coverage is given to the entire spectrum of sexually transmitted diseases, and an additional section on diagnostic perspectives offers never before published material on why this syndrome occurs primarily among homosexual men. For any physician or other health care professional interested in the prevention and cure of this modern epidemic, this book is an indispensable guide to recognizing and treating AIDS and other sexually transmitted diseases.

Table of Contents

• PART I SEXUALLY TRANSMITTED DISEASES — NONDIARRHEAL • PART 2 SEXUALLY TRANSMITTED DISEASES — DIARRHEAL • PART 3 OTHER SEXUALLY TRANSMITTED DISEASES • PART 4 INFECTIOUS AND NEOPLASTIC COMPLICATIONS OF AIDS • PART 5 IMMUNOLOGICAL EVALUATION METHODS AND CONTROLS • PART 6 DIAGNOSTIC PERSPECTIVE

Influence of the Aortic Component of the Second Heart Sound on Left Ventricular Maximal Negative dP/dt in the Dog

DAMON SMITH, BME, and ERNEST CRAIGE, MD

Maximal negative left ventricular dP/dt is widely used as a measure of isovolumic muscular relaxation of the left ventricle. In the course of canine experiments designed to elucidate the hemodynamic events responsible for the aortic component of the second heart sound, high-fidelity left ventricular pressure and dP/dt signals were recorded and accelerations detected on the root of the aorta and epicardium at the cardiac apex. The second heart sound was coincident with maximal negative dP/dt and affected its magnitude to a variable and unpredictable extent. This may account for some of the unexpected variations in magnitude of maximal negative dP/dt that have been described in various disease states and in laboratory experiments where the effects of physiologic and pharmacologic interventions have been studied.

(Am J Cardiol 1985;55:205–209)

The maximal rate of pressure reduction of the left ventricular (LV) pressure signal (maximal negative LV dP/dt) has been extensively used during the past 10 years[1–4] as an index of peak rate of LV relaxation. The determinants of maximal negative LV dP/dt have been studied in animal preparations under controlled conditions. This parameter has been found to vary directly with peak aortic pressure.[2,3] Other factors that have been proposed as having a significant influence are the intrinsic contractility and the end-systolic volume,[1] the rate and extent of fiber shortening during systole[3,5] and the adequacy of coronary perfusion.[6–15]

In patients with both aortic valve stenosis and regurgitation, Eichorn et al[16] found that maximal negative LV dP/dt was not significantly different from that in normal control subjects. This finding was unexpected and occurred although several conditions such as exaggerated peak LV systolic pressure and end-systolic volume index, which increase the maximal negative LV dP/dt, could be shown to be present.

In all the studies cited, the assumption is made that maximal negative LV dP/dt measures exclusively a feature of LV muscular relaxation during isovolumic relaxation. The potential contribution of intracardiac vibrations related to the aortic component of the second heart sound (A_2) was ignored or considered to be insignificant, although the LV dP/dt signal is recorded with a frequency response well into the range of frequencies occupied by the intracardiac A_2 vibration.

In the present report, based on experiments on the open-chest dog, we studied the possibility that the sharp negative spike of the LV dP/dt signal, which is a significant component of the total maximal negative excursion of the LV dP/dt signal at the onset of isovolumic relaxation, is largely an intracardiac pressure transient caused by aortic valve closure.

Methods

Experimental design for study of A_2: During studies concerning the hemodynamic aspects of the second heart sound, 18 mongrel dogs that weighed 20 to 35 kg were anesthetized with intravenous sodium pentobarbital and ventilated by means of a mechanical respirator. The dogs were placed in the supine position and a median sternotomy was performed. The pericardium was opened and sewn so as to create a pericardial cradle for the heart and to allow access to its anterior surface. The proximal aortic root was exposed by blunt dissection to provide clear access to its anterior surface. Aortic and ventricular pressure signals were detected through high-fidelity micromanometer-tipped catheters (Millar Instruments). The aortic catheter was inserted through the right external carotid artery, and positioned within 2 cm of the aortic valve. The ventricular catheter was inserted directly through the LV wall at the apex, and positioned in the apical

From the Department of Medicine, University of North Carolina School of Medicine, Chapel Hill, North Carolina. This study was supported by Grant 5 R01 HL27459-03 from the National Heart, Lung, and Blood Institute, Bethesda, Maryland, and the J.P. Riddle Fund of the University of North Carolina Medical Foundation, Chapel Hill, North Carolina. Manuscript received June 15, 1984; revised manuscript received August 16, 1984, accepted August 20, 1984.

Address for reprints: Damon Smith, Division of Cardiology, 338 Burnett Womack Building 229H, University of North Carolina School of Medicine, Chapel Hill, North Carolina 27514.

region of the ventricular chamber. The LV pressure signal was passed through an RC differentiation circuit with a time constant of less than 0.2 ms to obtain LV dP/dt. The pressure signals and the LV dP/dt signal were recorded on direct-current input channels of a multichannel physiologic recorder (Electronics for Medicine) with a frequency response bandwidth of 250 Hz. To detect heart and aortic surface dynamics at the time of the A_2 vibration, a miniature accelerometer was used. This accelerometer was of the bonded strain gauge type (Entran Devices), had 1 sensitive axis, and a sensitivity to accelerations at right angles to this of 3% or less of the prime axis sensitivity. The device senses accelerations with a frequency response from 0 to more than 300 Hz. The accelerometer and its associated plastic mounting plate together have a mass of about 1.0 g. The plastic mounting plate has a diameter of approximately 2 cm. We refer to the signal from the accelerometer as "SAA" and label it as such in the figures. The acceleration signal was recorded on the multichannel recorder with a frequency response from 1 to 250 Hz. The accelerometer instrument has been described previously.[17,18] In all 18 dogs, the accelerometer was attached to the anterior epicardial surface, near the apex, using cyanoacrylate glue. The sensitive axis was oriented perpendicular to the epicardial surface, so that inward and outward acceleration transients of the heart surface could be studied. The polarity of the acceleration signal from the apex position was recorded so that an upward excursion of the signal above the baseline was representative of an outward acceleration of the epicardium. In 5 of the 18 dogs, a second accelerometer was attached by cyanoacrylate glue to the anterior surface of the proximal aortic root, within 3 cm of the aortic valve. The sensitive axis of this accelerometer was oriented parallel to the aortic surface, so that accelerations of the aortic wall along the axis of blood flow could be studied. The polarity of the acceleration signal from the aortic surface was such that an upward excursion of the signal above the baseline was indicative of acceleration in the anterograde direction (away from the ventricle), and a negative excursion of the signal below the baseline was representative of retrograde acceleration (toward the ventricle). Thus, in these 5 dogs, a method was provided for the simultaneous analysis of the aortic and ventricular dynamics, in the specified directions, at the time of the A_2.

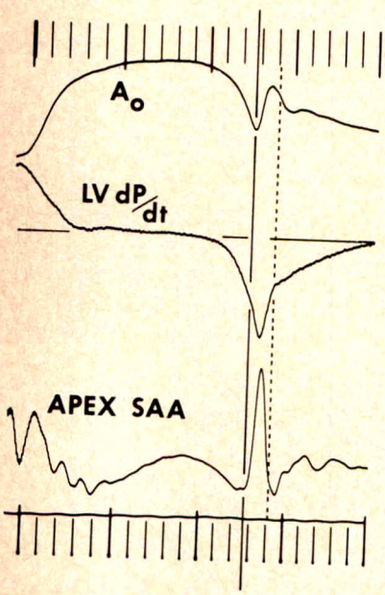

FIGURE 1. Simultaneous detection of the high-fidelity proximal aortic pressure signal (A_o) and the left ventricular (LV) dP/dt signal, along with the acceleration signal obtained at the anterior surface of the LV epicardium near the apex (APEX SAA). The timing of the LV dP/dt signal is accurate to within 0.11 ms for all frequencies. The instant of the incisural notch in the A_o signal is synchronous with the onset of the A_2 acceleration transient at the cardiac apex. The sharp negative spike of the LV dP/dt signal occurs during the time of this A_2 vibration. The termination of this vibration is coincident with a distinct transition in the slope of the LV dP/dt signal, as shown by the **dotted line.** This tracing was recorded at a paper speed of 500 mm/s and the thin lines are 10 ms.

Results

In all 18 dogs studied through the use of the miniature accelerometer, the nadir of the aortic incisura, at the instant of the beginning of the incisural upstroke, was simultaneous with the onset of an abrupt A_2 vibration of the LV epicardial surface near the apex. This vibration has a dominant frequency of approximately 100 Hz, which is consistent with the frequency range of A_2. As seen in the acceleration signal of Figure 1, this A_2 vibration is manifest as an outward acceleration transient of the epicardial surface near the apex. The exact synchrony of the beginning of this acceleration transient with the incisural notch of the aortic pressure signal is shown in the figure, which was recorded at a paper speed of 500 mm/s. The differentiation circuitry used to derive the LV dP/dt signal in this instance was such that the timing of the LV dP/dt signal was accurate to within 0.11 ms for all frequency components. As seen in Figure 1, the sharp negative spike of the LV dP/dt signal occurs during the time of the epicardial A_2 vibration. Furthermore, the termination of the A_2 vibration is associated with a distinct transition in the slope of the LV dP/dt signal, as shown by the dotted line in Figure 1.

In the 5 dogs instrumented with 2 accelerometers, the outward A_2 acceleration transient at the apex was also associated with an abrupt retrograde acceleration transient of the aortic surface, toward the left ventricle, as seen in Figure 2. In beat 2 of this figure, no aortic pressure pulse was produced, and the A_2 acceleration transients at both locations are totally absent.

Occasionally during these studies, the dogs would have pulsus alternans with alternating strong and weak beats. In 5 dogs, we obtained tracings in which some weak beats would exceed aortic pressure and produce an aortic pressure pulse and A_2 vibration, whereas other weak beats of similar or even greater contractile strength would fail to do so. Figures 3 and 4 demonstrate this situation, which allows for an assessment of the contribution of the intracardiac A_2 pressure fluctuation to the LV dP/dt signal. In Figure 3, the first 2 weak beats shown result in attenuated but distinct aortic pressure pulses, and the A2 acceleration transient in the acceleration signal. The sharp negative spike of the LV dP/dt signal that accompanies the A_2 transient is indicated by the arrows in these 2 beats. In the third weak beat of this figure, the LV pressure failed to exceed the aortic pressure and the aortic valve did not open. This is associated with a total absence of the A_2 transient at the apex, as noted in the acceleration signal, and a loss of the sharp negative spike of the LV dP/dt signal. The tracing shown in Figure 4 was recorded from the same dog at a time of increased end-diastolic LV pressure. The weak beats in this instance are stronger than the first 2 weak beats shown in Figure 3, but the weak beats shown in Figure 4 failed to produce the sharp negative

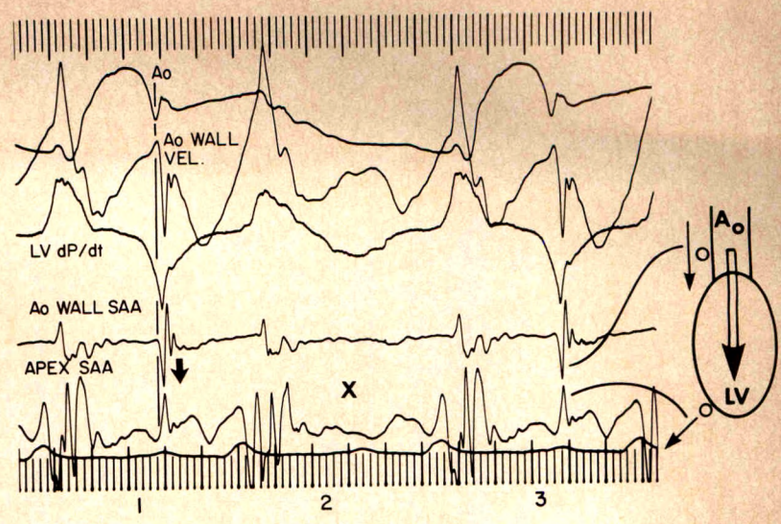

FIGURE 2. Dual accelerometer signals are obtained on the aortic root (A_o Wall SAA) and at the left ventricular (LV) apex (APEX SAA). A velocity (VEL.) signal is derived by electrical integration of the A_o Wall SAA signal, and indicated here as "A_o Wall Vel." The timing and direction of the accelerations at these positions at the time of the A_2 are indicated. At the instant of the A_o incisural notch an abrupt retrograde acceleration of the aortic root occurs and is associated with the acceleration transient observed at the apex. Beat 2 fails to cause an aortic pressure pulse (X) and is devoid of the A_2 accelerations observed in the normal beats. The hypothesized overall A_2 force vector is shown as the **large open arrow.** The **thin time lines** are 10 ms.

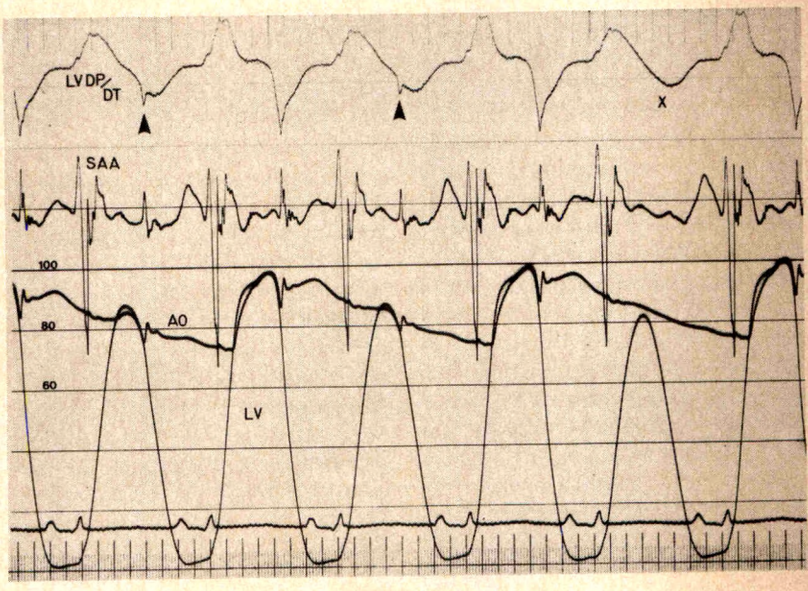

FIGURE 3. A tracing obtained during pulsus alternans in which the weak beats have a variable relation to the aortic pressure (AO). In the first 2 weak beats the left ventricular (LV) systolic pressure exceeds the aortic pressure and causes an aortic pressure pulse and A_2. The sharp negative spike component of the LV dP/dt signal during these beats is indicated by the **arrows.** The third weak beat fails to open the aortic valve. The A_2 vibration is absent in this beat, as shown by the acceleration signal at the apex (SAA). The association LV dP/dt signal is devoid of the sharp negative spike during this beat, as indicated by the X. The electrocardiogram lead II is at the **bottom.** Pressure calibration lines of 60, 80 and 100 mm Hg are shown.

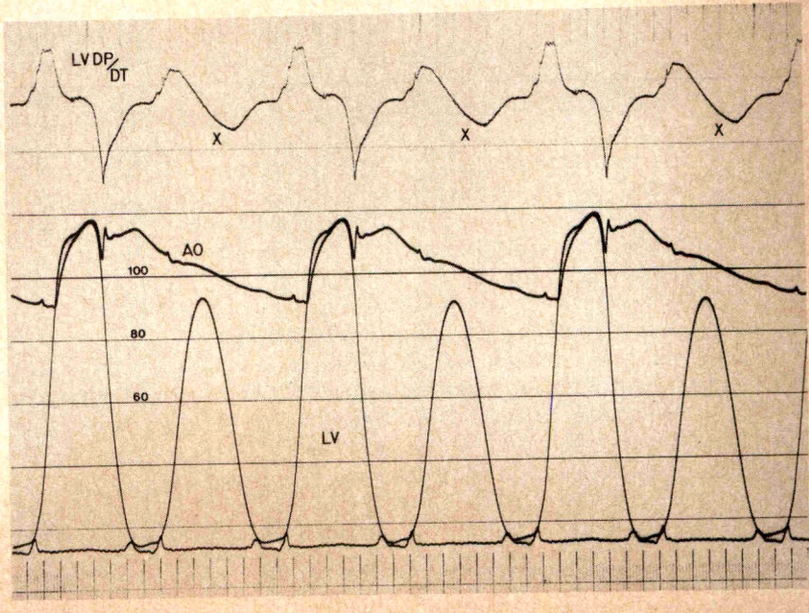

FIGURE 4. A continuation of the study shown in Figure 3, in which the end-diastolic pressure of the left ventricle has increased. The weak beats at this time are stronger than those in Figure 3, but fail to exceed the aortic (AO) pressure and open the aortic valve. As a result, the sharp negative spike component of the left ventricular (LV) dP/dt signal is totally absent as indicated by the X.

spike of the LV dP/dt signal because they did not open the aortic valve and result in an A_2 vibration.

Discussion

Historical perspective: The pioneer studies of Gleason and Braunwald in 1962[19] pointed out the potential use of measurements of dP/dt in assessing ventricular function and the effects of disease processes and pharmacologic interventions. Subsequent investigators have made extensive use of LV dP/dt measurements, initially in investigations of ventricular contraction[20] and, in recent years, ventricular relaxation.[1–4] In a meticulous canine study in 1974, Weisfeldt et al[2] established a close relation between the magnitude of maximal negative LV dP/dt and peak aortic systolic pressure. They were aware of the potential contributions to the dP/dt signal of aortic valve closure pressure transients, but concluded that maximal negative LV dP/dt occurred after the dicrotic notch, so as not to be contaminated by pressure fluctuations of valvular origin. In their subsequent elaboration of the important concept of "time constant T," which provides a measure of the entire time course of isovolumic pressure decrease after achievement of maximal negative LV dP/dt, Weiss, Frederiksen and Weisfeldt[3] noted that this factor does not depend on aortic valve closure. In a later study,[21] the same workers reiterated the observation that aortic valve closure appears to precede maximal negative LV dP/dt. Other investigators have adopted maximal negative LV dP/dt as an accurate measure of the rate of LV muscular relaxation without further concern over the contribution of intracardiac A_2 pressure fluctuations. Their studies have been done to establish the physiologic determinants of maximal negative LV dP/dt and modifying factors, which include inotropic state of the muscle, the volume of the heart at the moment of commencement of relaxation,[1] pharmacologic interventions,[5] coronary perfusion and ischemia.[6–15]

Intracardiac A_2 as studied by high-fidelity micromanometer: The A_2 vibration occurs predominantly in the frequency range of 33 to 111 Hz[22,23] and is manifest on the epicardial surface of the heart,[24] as well as in a pressure transient of the LV intracardiac blood mass.[25] Sabbah and Stein[36] studied the intracardiac A_2, using a micromanometer-tipped catheter inserted from the aorta, and thus passing through the aortic valve. They reported that the intraventricular pressure transient of A_2 was primarily a *pressurization* transient, based on observation of the direction of the vibration on their phonocardiogram. In our attempts to confirm this result, we obtained a signal of an intracardiac *pressurization* transient associated with aortic valve closure only when the distal portion of the manometer-tipped catheter was in obvious contact with the closing leaflets of the aortic valve, causing "hitting" or "catheter whip" artifacts. In our studies, we inserted the catheter directly into the LV chamber through the LV wall at the apex, to avoid the necessity of contact of the catheter with the aortic apparatus. When this was done, we were able to record clear intracardiac A_2 vibrations in the frequency range reported by others. Furthermore, the sharp negative *depressurization* component of the LV dP/dt signal constituted the intracardiac A2 pressure fluctuation, which occurred during the time of the epicardial A2 vibration and had a time period of approximately 10 ms (and, thus, a fundamental frequency of about 100 Hz) (Fig. 1). When we inserted the micromanometer-tipped catheter into the LV chamber from the aorta, with the tip away from the aortic valve, the same result was obtained. The requirement for the sharp negative spike component in the LV dP/dt signal of the weak beats of pulsus alternans is the production of an aortic pressure pulse and the associated A_2 vibration (Fig. 3 and 4). The weak beats of Figure 4 are stronger than those that exhibited the negative spike in Figure 3, but those in Figure 4 did not open the aortic valve and failed to produce the negative spike component.

The overall A_2 mechanism: The simultaneous study of aortic and heart surface dynamics provides insight into the nature of the overall A_2 mechanism. The accelerometer signal is proportional to the net force on the surface to which it is attached, acting along its sensitive axis. The instant of aortic repressurization, which defines the incisural notch, is associated with a distinct force on the aortic root pointing toward the left ventricle (Fig. 2). We believe the only reasonable explanation for the simultaneous appearance of aortic blood pressurization and retrograde force on the aortic root is an abrupt halting of retrograde blood movement by the closed and tensed aortic valve. This gives rise to an overall A_2 force vector, indicated in Figure 2 as the large open arrow. When the flow of fluid within a pipe is abruptly terminated by the sudden presence of a diaphragm instantaneously placed within the moving fluid column, the fluid colliding with the diaphragm causes the "water hammer" effect, producing a sharp pressurization transient within this fluid. Also, the fluid that is "down stream" to the diaphragm transiently pulls against the limiting structure as its momentum is halted, causing a sharp depressurization transient within this fluid. Furthermore, the force of deceleration of this flow, acting on the diaphragm, is transmitted into an overall force acting along the pipe in the direction of the blood flow at the instant of termination of this flow. Sabbah and Stein[27] showed through superb high-speed cinematography, that the flexible aortic valve develops transient but significant retrograde velocity as the valve seats. The pressure fluctuations and force transients that we have observed on and within the aortic and LV chambers are consistent with the concept that the dominant A_2 force arises from abrupt halting of the associated retrograde blood momentum when the valve reaches the limitation of its seating movement.

Temporal relation of A_2 and maximal negative LV dP/dt: The principal basis for ignoring the possible involvement of A_2 in the determination of maximal negative LV dP/dt was the observation that the achievement of the maximal negative excursion of the dP/dt signal occurred after the closure of the aortic valve and the onset of the A_2 vibration.[3] However, our

results show that the nadir of the sharp negative spike of LV dP/dt occurs during the time of the ventricular epicardial A_2 vibration at the apex, and that its timing is consistent with the hypothesis that it is associated with A_2. Perhaps the strongest argument in favor of this hypothesis, in terms of timing considerations, is the abrupt transition in the slope of the LV dP/dt signal that occurs at the termination of the epicardial A_2 vibration (dotted line in Figure 1).

Implications regarding hemodynamic determinants of A_2 intensity: The maximal dP/dt across the aortic valve is correlated with the magnitude of maximal negative LV dP/dt,[28] and has been reported to be the best hemodynamic determinant of A_2 intensity.[28,29] If the sharp negative spike of the LV dP/dt signal is simply the intracardiac manifestation of A_2, the maximal negative LV dP/dt and the maximal dP/dt across the valve are perhaps not *determinant* of A_2 size, but are, instead, largely *dependent* on A_2 size. Our results, and the hypothesis that the A_2 vibration results from the water hammer phenomenon, suggest that the cause-effect relation is reversed as compared with that proposed in these earlier studies.[28,29] Conditions known to be associated with reduced A_2 intensity, such as aortic valve stenosis and incompetence, would have a smaller than expected maximal negative LV dP/dt. We believe that this is the explanation for the finding by Eichorn et al[16] that maximal negative LV dP/dt was smaller than predicted in patients with these conditions. This does not deny the possibility that impaired muscular relaxation results in reduced A_2 intensity, as reported by Stein et al.[28]

Interlaboratory variability of instrumentation: The contribution of the sharp negative spike to the LV dP/dt signal is dependent on the frequency bandwidth of the recorded signal. Lack of standardization of this equipment further complicates the subject of maximal negative LV dP/dt and the involvement of the A_2.

Morphologic Changes Induced by Dilation of the Pulmonary Valve Anulus with Overlarge Balloons in Normal Newborn Lambs

JOHN C. RING, MD, THOMAS J. KULIK, MD, BARBARA A. BURKE, MD, and JAMES E. LOCK, MD

The optimal method for balloon dilation valvuloplasty of congenital pulmonary valve stenosis has not been established. The cardiac damage produced by using a balloon the same size as the pulmonary anulus has not been described. The use of balloons that are larger than the anulus or of a dynamic dilation technique may enhance gradient reduction, but their added risks are not known. The pulmonary valve anuli of 14 normal newborn lambs were dilated with angioplasty balloons 20% smaller to 90% larger than the anulus; in 3 dilations, a dynamic technique was used, consisting of withdrawal of the fully inflated balloon from the anulus into the body of the right ventricle. Twelve lambs were killed immediately after the procedure and 2 were killed later, and detailed gross anatomic and microscopic observations of the heart were made. These observations support the following conclusions: (1) Dilation of the pulmonary valve anulus with overlarge balloons is "clinically" well tolerated in normal newborn lambs. (2) The major damage to the heart from any balloon is not to the pulmonary anulus, but to the right ventricular outflow tract and free wall, with mural hemorrhages of varying size. (3) Trauma is minor if the balloon is 30% larger than the anulus, but is considerable when the balloon is 50% larger; (4) Trauma is worst subjacent to the proximal end of the balloon, so that longer balloons may cause greater damage; and (5) Resolution of acute right ventricular hemorrhage occurs with small, patchy areas of fibrosis.

(Am J Cardiol 1984;55:210–214)

Balloon dilation angioplasty is an invasive, but nonsurgical, technique that has been applied to the treatment of many types of acquired and congenital stenotic lesions in humans.[1–11] Results are often comparable to those after surgery, and the procedure can be safe and cost-effective. Several groups have adapted dilation techniques to the treatment of congenital pulmonary stenosis.[12–16] Gradient relief has, at times, been less than that which results from standard surgical procedures, thus potentially limiting the applicability of this otherwise promising new therapy. Balloons used for balloon dilation valvuloplasty (BDV) have been arbitrarily limited in size to no larger than the pulmonary valve anulus (PVA) itself.[12–15] The cardiac trauma that may result from this procedure has not been described. Dilation technique most often has consisted of static inflation of the balloon across the valve; a dynamic ("Rashkind-type") maneuver has been infrequently used.[16] Our experience with balloon dilation of peripheral pulmonary artery stenosis and coarctation of the aorta in humans and lambs suggests that more complete gradient relief can result from the use of overlarge balloons.[9,10,17,18] What is not known, however, is the largest balloon, relative to the size of the anulus, that can be used without producing an unacceptable degree of cardiac trauma. Therefore, we correlated in the lamb the type and extent of heart injury resulting from BDV of the pulmonary valve with balloon size and dilation technique.

Methods

Normal newborn lambs of either sex, aged 3 to 25 days (mean 12) that weighed 3.5 to 7.8 kg (mean 5.4), were sedated with intramuscular ketamine (2 mg/kg) and restrained. While breathing room air spontaneously a No. 6Fr angiocatheter was placed percutaneously in the right ventricular (RV) outflow tract. Iodinated contrast material, 2 mg/kg, was injected over

1 second and a single-frame lateral right ventriculogram was obtained. The diameter of the PVA was measured directly from the angiogram at the base of the sinuses of Valsalva (Fig. 1) and corrected for magnification using a radiopaque marker of known diameter. Then we placed a 0.032-inch Teflon-coated guidewire far distally in a branch pulmonary artery. A dilation catheter (Meditech) was then advanced over the guidewire until the balloon was centered in the PVA. In 11 lambs, the balloon was inflated in situ with dilute contrast material to a pressure of 5 to 6 atm for 10 seconds, then rapidly deflated; in 3 lambs, static inflation was followed by a dynamic maneuver, in which the inflated balloon was drawn briskly back 1 to 2 cm into the body of the right ventricle before dilation. Dilation balloons, mounted on 8Fr semiflexible catheters, were made of polyethylene, were 3 to 4 cm long, had a maximal inflated diameter of 15 or 20 mm, and were 20% smaller to 90% larger than the PVA when fully inflated. After dilation, a second right ventriculogram was injected to determine any change in anulus size and to look for extravasation of contrast material and tricuspid valve insufficiency.

Twelve lambs were killed, electively, 20 to 30 minutes after dilation, and 2 were killed late (83 and 111 days) after the procedure. The pathologist's examination, performed without knowledge of balloon size or dilation technique, included a detailed description of the gross anatomy, with particular emphasis on the right side of the heart. Tissue sections were taken for light microscopy from the right atrium/atrioventricular node, tricuspid valve, RV free wall and outflow tract, pulmonary valve, and pulmonary artery, and stained with hematoxylin-eosin. Statistical analysis of the data was not performed.

* Static dilation; † dynamic dilation.

Results

Balloon dilation acutely occluded the RV outflow. Although some degree of systemic hypotension, bradycardia, ventricular ectopy, and restlessness of the animal ensued, none of the lambs required respiratory or hemodynamic support. Similar findings have been reported in dogs[19] and in children,[13,15] even though balloons smaller than the size of the anulus were used. Both of the lambs killed late grew normally and neither had late evidence of hemodynamic compromise.

Follow-up angiography did not show tricuspid insufficiency or extravasation of contrast material. Table I relates the change between the angiographically determined pre- and postdilation PVA size to balloon size and dilation technique. In general, little change in PVA size occurred, regardless of the size of the balloon used or the dilation technique.

The degree of cardiac trauma associated with the procedure was directly related to the size of the balloon used and allowed separation of the lambs into 2 groups.

Group 1 included seven lambs dilated with balloons 20% smaller to 40% larger than the size of the PVA. Two dilation procedures were dynamic and 1 lamb in group 1 was killed late. The gross pathologic findings in this group are summarized in Table II. Acutely, dilations with balloons this size produced small, mostly superficial areas of subendocardial hemorrhage largely confined to the RV outflow tract and free wall, subjacent to the proximal end of the dilation balloon (Fig. 2). Even within this group, there was a tendency for balloons more than 30% larger than the size of the anulus to cause more extensive damage. The heart dilated with the balloon slightly smaller than the size of the anulus was

injured as much as those dilated with balloons slightly larger. The pulmonary valve itself and the proximal pulmonary artery were undamaged in all specimens. Minute, superficial hemorrhages were seen in the anterior leaflet of the tricuspid valve in 2 lambs. Small hemorrhages were also noted at the inferior vena cava–right atrial junction in 2 lambs and in the right atrial appendage of a third, presumably related to catheter passage. The dynamic technique was associated with injury to the RV inflow tract not seen with static dilation using balloons of comparable size. Grossly, the heart of the lamb killed late was normal except for a small area of endocardial thickening.

Group 2 includes 7 lambs dilated with balloons 50 to 90% larger than the size of the anulus. One dilation was performed with dynamic technique and 1 lamb was killed late. The gross pathologic findings in these specimens are recorded in Table II. More extensive cardiac trauma was noted in these hearts and, again, the most marked changes were seen in the RV outflow tract and free wall, subjacent to the proximal end of the dilation balloon; other cardiac structures, however, were more likely to be damaged, too. Hearts from 5 of the 6 lambs evaluated acutely showed transmural hemorrhages that, in general, covered a larger area of the RV free wall (Fig. 3). In contrast to the hearts of the lambs in group 1, 5 of the 6 specimens in group 2 evaluated acutely showed hemorrhage in 1 or more cusps of the pulmonary valve; in 2 hearts, hemorrhage induced valve distortion that may have led to pulmonary insufficiency. The tricuspid valve was normal in all the hearts. Small hemorrhages were seen in the right atrium in 4 hearts, including 1 heart in which hemorrhage was near the expected position of the atrioventricular node. Three hearts demonstrated hemorrhage in the RV inflow tract, especially in the papillary muscle of the conus. Cardiac trauma in the specimen dynamically dilated was no greater than that seen in other specimens statically dilated with balloons of the same size. Again, no gross anatomic abnormalities were noted in the heart of the lamb killed late.

The most extensive cardiac trauma occurred in the heart dilated with a balloon nearly twice the size of the anulus. Although hemorrhage was seen in most structures in this heart, the most intimidating finding was

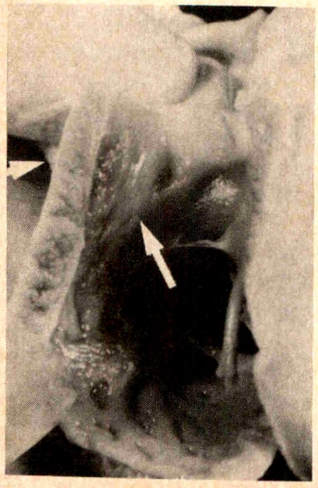

FIGURE 2. Pathologic specimen of a heart in group 1. The right ventricular outflow tract and pulmonary artery are opened, with the base of the heart at the top of the picture. The **arrows** point toward a very small subendocardial hemorrhage in the free wall. The pulmonary valve cusps are normal.

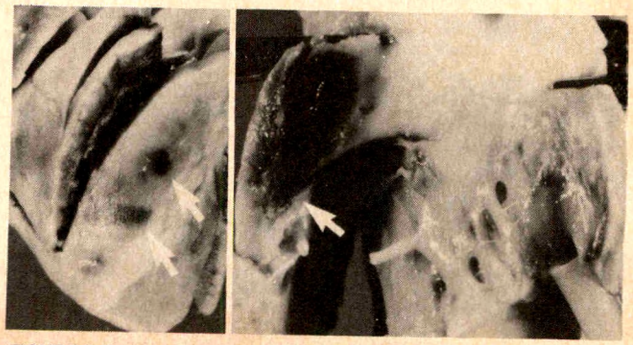

FIGURE 3. Pathologic specimens of hearts in group 2. **Left,** hemorrhage is distributed more widely in the free wall (**arrows**). **Right,** detail of large, transmural hemorrhage in the free wall (**arrow**).

a gaping laceration that extended from the RV outflow tract through the pulmonary valve out to the bifurcation of the pulmonary artery (Fig. 4). Hematoma completely enveloped both great vessels.

Histopathologically, the most marked changes were seen in the RV free wall and outflow tract, then in the pulmonary valve itself. Findings were largely limited to varying degrees of fresh, subendocardial interstitial hemorrhage, though an occasional mural thrombus or focus of endothelial denudation or fibrin deposition was sectioned. Trauma was increased in severity histologically when dilation was performed with larger balloons or dynamic technique. Of interest were small, patchy areas of fibrosis seen in the RV free wall—the area of greatest acute trauma—of both lambs killed late; all other structures in these 2 hearts, however, were normal microscopically. No hemorrhage was found in the atrioventricular node, even in the heart in which, by gross pathologic examination, it was anticipated.

Discussion

BDV may be a safer and more cost-effective mode of therapy than surgery for congenital pulmonary stenosis, but it cannot be considered the treatment of choice unless an equivalent gradient reduction can be achieved and there are no long-term adverse sequelae. Larger dilation balloons and dynamic dilation technique exert more force against the stenotic valve and may, therefore, afford greater gradient relief. These technical modifications, however, may increase the risk of significant, acute cardiac trauma, including tricuspid or pulmonary valve insufficiency, RV dysfunction, uncontrollable hemorrhage in the closed thorax, or frank cardiac rupture.

Clinically, BDV with overlarge balloons is well tolerated by normal newborn lambs. Acutely, there were no signs of sustained low cardiac output and lambs killed late grew normally. These observations mitigate strongly against significant tricuspid or pulmonary valve insufficiency or RV dysfunction being produced by the procedure. They also indicate that the absence of clinical signs of cardiac trauma does not ensure an uninjured heart after dilation.

Pathologically, this study indicates that dilation with balloons up to 30% larger than the size of the anulus is associated with minimal cardiac trauma, while dilation with balloons 50 to 90% larger produces substantial heart injury. Although the data are limited, it appears that no further protection is afforded the heart by using balloons smaller than the size of the anulus. Trauma is largely limited to areas of the right ventricle subjacent to the proximal end of the balloon and appears to be related to the balloon straightening against the curvature of the outflow tract (Fig. 5). Balloons longer than 3 cm, therefore, may cause more extensive injury. Dynamic dilation technique, at least with balloons up to 30% larger than the anulus, may be associated with a greater degree of heart injury, especially in the RV inflow tract. This technique adds somewhat to the risk of the procedure and, if used, should be reserved for stenoses refractory to static dilation.

One late risk of BDV may be resolution with fibrosis of acute hemorrhage in the RV outflow tract and free wall. Other investigators have implicated extensive RV fibrosis as a factor that predisposes patients with repaired tetralogy of Fallot to ventricular dysrhythmias.[20] Though the degree of fibrosis observed in these cardiac specimens was considered less extensive than that seen in human hearts after tetralogy repair, the possibility that BDV may contribute to the genesis of late dysrhythmias cannot be excluded. The probability of late tricuspid insufficiency appears low, but cannot be excluded.

This study has several limitations. Because only single-frame angiograms were obtained, we cannot rule

FIGURE 4. Pathologic specimen of the heart dilated with a balloon 90% larger than the anulus. The **arrow** denotes a through-and-through laceration that extends from the right ventricular outflow tract to the pulmonary artery bifurcation. Hematoma surrounds the great vessels.

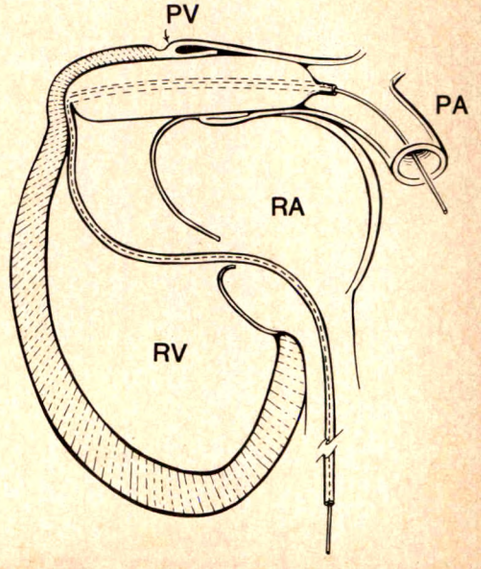

FIGURE 5. A right ventricle (RV) and pulmonary artery (PA) (lateral view), with the dilation balloon superimposed. Note that balloon inflation causes the proximal end of the dilation balloon to distort the curvature of the right ventricular free wall. PV = pulmonary valve; RA = right atrium.

out mild tricuspid insufficiency with confidence. Because only 1 or 2 lambs were studied at any given balloon size, we cannot be too precise in our discussion of balloon limits. The hypertrophied right ventricle may respond to BDV differently than the normal right ventricle and a stenotic pulmonary valve might "protect" the anulus from injury. Nonetheless, we conclude that the use of overlarge balloons—no larger than 30% greater than the size of the anulus—produces a minimal degree of cardiac trauma, and may improve the hemodynamic results of BDV.

Acknowledgment: We thank Donna Howland, Joseph Rysavy and Robyn Shutjer for their expert technical assistance in performing the study and Joan Baber, Sandra Caughey and Ileana Fishlin for preparation of the manuscript.

Potential Limitations of Quantitative Thallium Scanning

DAVID M. McCARTHY, MD, and P. TODD MAKLER, Jr., MD

Myocardial perfusion imaging with thallium-201 (Tl-201) has become an accepted technique for evaluating patients with known or suspected coronary artery disease (CAD).[1] This technique is frequently performed in conjunction with exercise stress testing. Perfusion images are obtained immediately after stress and after a 2- to 4-hour redistribution time.[2] The images are examined for the presence of either fixed (scar) or reversible (ischemic) perfusion defects.

When interpreted visually, Tl-201 scintigraphy is reasonably accurate for detecting areas of scar,[3] and is significantly more accurate than stress electrocardiography for diagnosing CAD.[4] However, visual Tl-201 scanning is less accurate for predicting the number of involved vessels[5] or for detecting disease in specific coronary arteries.[6] These are significant limitations, because CAD prognosis relates in part to the extent of disease,[7] and coronary artery bypass grafting may improve survival in subgroups of patients with specific disease patterns.[8] In addition, visual interpretation of Tl-201 scans is often difficult and subject to significant inter- and intraobserver disagreement.[9]

To address some of these shortcomings, some investigators have proposed quantitative methods for analyzing planar Tl-201 scans,[10,11] based on the assumption that the myocardial concentration of the isotope is proportional to local tissue blood flow, and can be determined by the counting rate at the camera face. The initial encouraging reports of quantitative thallium scanning[12,13] have resulted in their widespread clinical use. This review points out some potential limitations of these methods.

Methods of Quantitative Analysis

The principal quantitative techniques are horizontal[10] and circumferential[11] profile analysis. Because the techniques are different they will be described briefly. In both methods, initial image processing involves background subtraction, which is designed to isolate "true" myocardial Tl-201 activity from nonmyocardial scatter. Once the "net" (background-subtracted) myocardial image is obtained the 2 methods diverge. In the *horizontal profile* routine[10] the operator identifies the superior and inferior myocardial walls, and the computer automatically generates horizontal slices at those 2 levels and at 2 evenly spaced levels in between, for a total of 4 horizontal slices that measure the radioactive counts at each specific level. This operation is performed on both the stress and redistribution scans, and the patterns of Tl-201 uptake and washout are assessed against normal established limits.[12]

The other major method of Tl-201 quantification involves the generation of *circumferential profiles*.[11] After background subtraction, the operator marks the center and, in some programs, the apex of the left ventricle; the computer searches radially from the center to the myocardial wall for the peak counts, which are then plotted, usually for sixty 6° sectors to comprise the entire circumference of the heart. Again, this is performed on both the stress and redistribution images, and the results are interpreted according to established criteria.[13]

Either of these methods is at least as accurate as visual analysis for detecting CAD, and significantly more accurate for determining the presence of multivessel disease and lesions in specific coronary arteries.[12,13] In addition, these techniques are assumed to be more reproducible than visual scan interpretation. In fact, we recently studied the reproducibility of circumferential profile analysis,[14] and found that the intraobserver variability (1 observer recalculating profile curves on the same scan) averaged 4.9%, whereas interobserver variability was 5.4%.

Potential Problems with Quantitative Analysis

Quantitative Tl-201 scan analysis is predicated on several assumptions that may not always be true. This can lead to potential problems in interpretation, which will be discussed.

Background subtraction: As noted previously, background subtraction is used in both quantitative methods in order to create a net myocardial image that contains only true heart counts. The subtraction algorithm is generally some modification of the interpolative technique of Goris et al,[15] in which the noncardiac activity in a rectangular region surrounding the heart is used to estimate the noncardiac activity over- and underlying the heart, which is subtracted (pixel by

pixel) from the heart tissue. This assumption was tested by Narahara et al,[16] who performed Tl-201 scans in dogs before and after removing the heart and replacing it with a balloon that was filled with either water or air. The true background (in the images performed after the heart had been removed) was compared with that estimated by the interpolative approach, and the investigators found that the computer algorithm consistently overestimated the true background activity, which resulted in considerably fewer myocardial counts in the background-subtracted image than were present in the heart scanned in situ. They concluded that caution should be used when subtracting background from Tl-201 images, in particular when there is considerable activity in adjacent organs (e.g., the liver or spleen); in this situation, erroneous regional perfusion defects could result.

Another potential problem with background subtraction occurs when the lung uptake of Tl-201 is increased; this finding is sometimes observed on the stress images in patients with severe CAD, and is probably due to exercise-induced left ventricular dysfunction.[17] Rothendler et al[18] evaluated the potential error in Tl-201 washout caused by increased lung uptake. They simulated increased lung uptake by superimposing technetium-99m-labeled albumin scans on delayed Tl-201 heart images, and compared the net myocardial activity after background subtraction in the same Tl-201 scan with and without the superimposed lung uptake. There was an average 36% increase in myocardial activity in the images without lung activity (due to overestimation of background in the scans with increased "lung uptake"), and the overestimation varied in different regions of the heart, from 18 to 69%. The investigators concluded that this could result in significant errors in calculating regional washout rates of Tl-201. Thus, not only is there the potential for error in the estimation of background, but this error can be compounded in patients with increased lung Tl-201 activity on the images immediately after exercise.

Repositioning variability: Because quantitative Tl-201 analysis is performed on 2 images, 1 immediately after exercise and one 2 to 4 hours later, another potential source of error is the position of the patient relative to the gamma camera. Although standard views are used and the camera head can be adjusted to the same angle, the contribution of variability in repositioning has not been extensively studied. Even when software that allows for apex identification (to correct for rotatory inconsistency) is used the variability of scans performed several hours apart can be substantial.

We evaluated the effect of patient repositioning in 19 patients who had 2 separate redistribution scans performed in the 40° left anterior oblique view.[14] The technologists were instructed to duplicate the position as carefully as possible, and the redistribution scans were chosen for analysis, since there should be little change in Tl-201 activity between 2 scans performed several hours after injection. The 2 scans were analyzed using the circumferential profile method, and there was 12.9% variability in the curves. Even when the variability of reanalysis was taken into account, there was an implicit repositioning variability of 11.5%. Thus, quantitative comparison of 2 scans will have a degree of variability that is independent of the operator or the software.

Level of exercise: Quantitative analysis of exercise and redistribution Tl-201 scans requires that the count profiles and curves be compared with "normal limits" of uptake and washout, values determined in normal patients undergoing Tl-201 imaging. However, patients with CAD often cannot perform the same level of exercise as normal subjects, and the level of myocardial oxygen consumption, coronary blood flow and Tl-201 uptake may be different, not as a consequence of ischemia but because of the different level of stress. Massie et al[19] studied normal subjects on 2 occasions: The first test was a symptom-limited maximal stress test, and the second test was stopped after only one-half of the exercise duration on the maximal test. Thallium-201 exercise and 3-hour redistribution scans were performed in conjunction with both stress tests, and Massie et al found that the washout rate (over 3 hours) was significantly greater on the maximal test than on the submaximal test. In some patients with CAD who exercised submaximally because they reached nonischemic endpoints (e.g., claudication), the washout rates were abnormal in regions *unaffected* by diseased coronary vessels. The investigators concluded that the normal limits of washout, which have been established in normal subjects who have exercised maximally, cannot be used to evaluate Tl-201 washout in patients who exercise submaximally, stopping for nonischemic reasons.

Redistribution kinetics: The observation that Tl-201 activity in the myocardium changes over time has altered the test such that redistribution scans are routinely performed 2 to 4 hours after exercise and are used as the comparison scans for interpretation.[20] This characteristic is 1 of the fundamental principles that has made quantitative analysis feasible, and is used for calculating "washout rates," which are then interpreted for detection of CAD.[12,13] However, patterns of Tl-201 redistribution are variable. Early redistribution of stress-induced defects has been reported both by visual inspection[21] and by quantitative analysis,[22,23] findings that have important implications on when imaging immediately after exercise should commence. However, some defects demonstrate "late" (18 to 24 hours) redistribution; these are generally in regions supplied by severely stenosed coronary arteries, yet with normal wall motion and no evidence for myocardial infarction.[22] Thus, if Tl-201 uptake and washout rates are determined from only 2 scans (i.e., exercise and 2- to 4-hour redistribution), possible errors in assessing tissue viability may result.

Conclusion

Quantitative planar Tl-201 scanning appears to offer advantages over visual scan interpretation, although several factors may affect the results. Although these do not preclude the usefulness of the approach, they should be considered when quantitation is used, espe-

cially in borderline cases or in certain types of patients (e.g., those with increased lung uptake or those who exercise only to submaximal levels because of non-ischemic causes). The newly emerging technique of single-photon emission-computed tomography (SPECT)[24] can also be analyzed quantitatively.[25] Potential problems with background subtraction and excessive lung uptake should be overcome with SPECT imaging; however, SPECT imaging requires specialized equipment that is not yet available in all laboratories. For those using planar quantitation, attention to the limitations should minimize artifactual errors.

On Pulmonary Vascular Resistance: The Need For More Precise Definition

MAURICE McGREGOR, MD, and ALLAN SNIDERMAN, MD

The term vascular resistance describes, in part, the forces opposing the flow of blood across a vascular bed. It is well recognized that a change of resistance does not necessarily indicate vasomotion. It is less well recognized, however, that resistance as commonly calculated can *appear* to change without any change taking place in any of the forces opposing flow. Since this is a pure artifact of the calculation, it is important that it be understood.

From the McGill University Clinic and the Cardiovascular Research Unit, Royal Victoria Hospital, Montreal, Quebec, Canada.

Manuscript received June 4, 1984; revised manuscript received September 11, 1984, accepted September 13, 1984.

Address for reprints: Allan Sniderman, MD, Cardiovascular Research Unit, Room M4.14, Royal Victoria Hospital, 687 Pine Avenue West, Montreal, Quebec H3A 1A1, Canada.

Conceptually vascular resistance is comparable to electrical resistance as defined by Ohm's law. The resistance offered by a conductor to the flow of current is a constant, expressed by the voltage drop over any defined distance for any current flow. The resistance of a hydraulic system can be similarly expressed as the ratio of the pressure drop from some upstream point to a downstream point divided by the flow. For fully developed steady flow in a system of smooth walled, regular, nondistensible tubes in which flow is laminar, resistance to flow will be constant and the plot relating change in pressure to change in flow will be a straight line, the slope of which defines the resistance. A shallow slope will indicate a low resistance and a steep slope will indicate a high resistance (Fig. 1a). The ratio of pressure to flow will be constant over a wide range of flows and

can reasonably be referred to under these circumstances as the "resistance" of the system.

In a system in which, instead of being rigid, the vessels which offer resistance to flow are compliant, volume and radius will increase with increasing pressure. Thus, resistance will decrease as pressure increases and the pressure:flow plot will be curved with a diminishing steepness at increasing flows. The resistance will no longer be constant and the flow:resistance plot will reflect progressively lower resistances at higher levels of flow (Fig. 1a). Similarly, if rising pressures cause sequential opening of new parallel vascular pathways (recruitment), resistance will also fall as flow increases.

The pulmonary vasculature is widely considered to behave in this way. As expressed by a contemporary textbook, "as flow increases, pulmonary vascular resistance (PVR) decreases. Consequently, irrespective of whether distention or recruitment occurs, both mechanisms subserve the necessity of maintaining a low pressure circuit during situations of increased blood flow."[1] This description of the pulmonary vasculature, however, is only partly correct and is largely based on erroneous interpretation of experimental data.

There are, of course, published pressure:flow curves that display alinearity, particularly at the lower range, as pulmonary flow is lowered from low normal to 0.[2] However, over the operating range of pressure and flow the evidence indicates that, at least in the dog lung, the slope is either constant,[3,4] or only slightly curvilinear.[2] Thus, resistance is virtually constant, and a decreasing resistance cannot be invoked to explain the absence of pulmonary hypertension at high flows in the normal lung.

The belief that the absence of pulmonary hypertension at high flows is due to recruitment or dilatation of resistance vessels is largely the result of ignoring the existence of a significant "critical closing pressure" in the lung. That is to say, with progressive reduction of pulmonary arterial (PA) pressure, blood flow may cease while PA pressure is still higher than left atrial (LA) pressure. This may be a result of the forces on the outside of the vessels, such as the alveolar pressure on the pulmonary capillaries in zone 2 of the normal lung,[5] or due to elastic or muscular recoil of the vessel wall itself, as occurs in some forms of pulmonary hypertension. Whatever the cause, some pressure is necessary to open the vessels in order for blood to flow, and this has been called the critical opening or closing pressure, or simply the critical pressure.[6]

In a system in which there is a constant resistance and a critical pressure of, say, 10 mm Hg, the pressure-flow plot will intercept the pressure axis at 10 (Fig. 1b). The "resistance" of such a circuit must, as pointed out by Permutt, Bromberger-Barnea and Bane,[7] then be calculated by dividing flow, not into PA pressure nor into the difference between PA and LA pressure, but into the difference between PA pressure and critical pressure, since this is the effective downstream pressure of the system.

If the critical pressure is unknown or ignored and flow is divided into the difference between PA and LA pressure an interesting error is introduced. The pressure:flow plot will still be linear, indicating the absence of any change in true resistance as flow increases (Fig. 1b). The calculated pressure:flow ratio will, however, decrease as the flow increases (Fig. 1b).

Failure to understand this has led to erroneous conclusions about the nature of the pulmonary bed. An example is the study of Borst et al,[3] a diagram of which is reproduced in Figure 2. This diagram shows the relation between PA pressure and flow in the left lung of an anesthetized, open-chest dog ventilated with an end-expiratory pressure of 3.7 mm Hg. The pressure-flow plot is almost linear, indicating that resistance to flow was virtually constant throughout the range of pressures and flows studied. However, in calculating values for resistance, a critical pressure of approximately 12 mm Hg was ignored and PA pressure less LA pressure was divided by flow. In consequence, the ap-

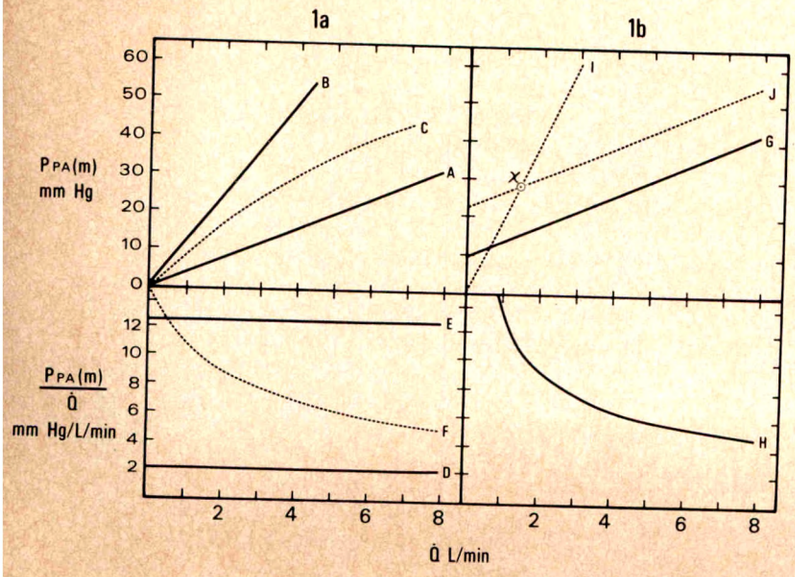

FIGURE 1. Relation between pulmonary flow per lung (Q̇ L/min) and pulmonary artery mean pressure ($P_{PA}(m)$) (**top**) and pulmonary pressure:flow ratio per lung ($P_{PA}(m)/\dot{Q}$) (**bottom**). See text.

parent resistance (the pressure:flow ratio) *appeared* to fall as flow increased, leading Borst et al to conclude, "there was a rapid reduction of resistance as PA pressure increased." It is almost entirely the artifact included in this calculation that has led to the belief that PVR decreases significantly as flow increases. Indeed, there has been much debate as to whether this fall is the result of distention or recruitment of the vascular bed.[8] It is of course the result of neither, but is the consequence of using the incorrect downstream pressure.

In intact man the pressure:flow relations of the normal pulmonary vascular bed are harder to study than in the dog. Consideration of data derived from exercising, supine subjects reported by Bevegard, Holmgren and Jonsson[9] suggests a pressure:flow slope in normal man of about 1.5 mm Hg/liters/min/m^2/min. Unfortunately, exercise introduces other variables, such as changes in LA pressure. These problems can be avoided in the resting supine individual by inflating a balloon so as to obstruct one pulmonary artery. In this way the total cardiac output is directed through the opposite lung. If the assumption is made that flow is divided equally between the 2 lungs and that the intervention causes no disturbance of cardiac output or pulmonary vascular tone, one can use the 2 pressure:flow points obtained before and after balloon inflation to define the resistance of the unoccluded lung over the range in question.[10]

Average points from 6[11] and 4[10] normal persons are shown in Figure 3. Extension of data such as this over a wider range, which can be done by initiating exercise while 1 pulmonary artery remains blocked, suggests that linearity is maintained.[11] Extrapolation from these points to 0 flow suggests an average normal critical pressure of the order of 10 mm Hg. The slope of the pressure-flow plots is about 3.3 mm Hg/liters/min/m^2/lung and the average resistance of the 2 lungs in parallel is thus half this value, or 1.6 mm Hg/liters/min/m^2.

When we consider clinical pulmonary hypertension, it is apparent that with normal LA pressure, raised PA pressure could result either from elevation of critical pressure or from an increase in the true resistance (increased steepness of the pressure:flow plot) or from both. For example, a PA mean pressure of 30 mm Hg and a cardiac index of 3 liters/min/m^2 (or approximately 1.5 liters/min/m^2/lung), point X may be the consequence of a high resistance with a normal critical pressure or of a normal resistance with an elevated critical pressure (Fig. 1b).

Depending on which mechanism is predominant, there will be major differences in the way pressure re-

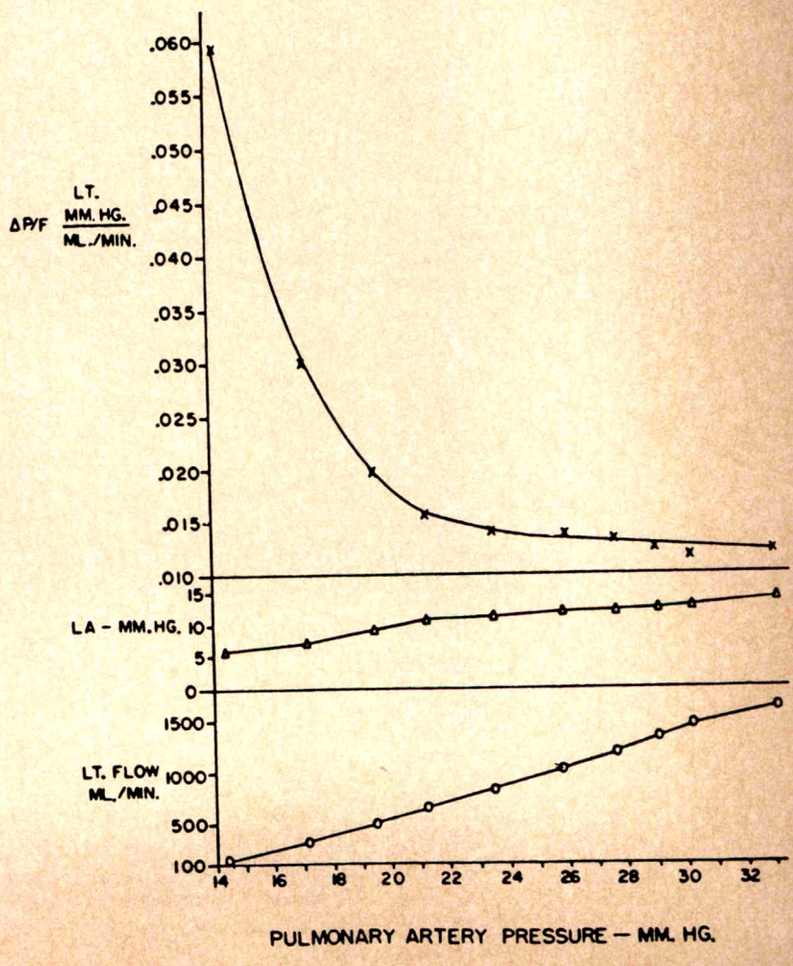

FIGURE 2. Relations between pulmonary artery mean pressure and pulmonary pressure:flow ratio (P/F), left atrial mean pressure (LA) and the flow to the left lung (LT). Flow values are from the study of Borst et al.[3] Increment of pulmonary artery pressure with flow is linear. True resistance is thus constant; but "resistance" as reflected by the pressure:flow ratio falls steeply with increasing pulmonary artery pressure.

sponds to increased output. Thus, if pressures at rest are elevated solely as a result of high critical pressure (Fig. 1b), pulmonary flow could well double without any major increase in pressure. If, however, the pulmonary hypertension were due to an increase in true resistance any increase in flow would be associated with major increments of pressure (Fig. 1b).

The limited clinical data available are consistent with this distinction. For example, average values from 5 patients with pulmonary hypertension due to chronic bronchitis and emphysema and 4 patients with mild to moderate mitral stenosis[11] (Fig. 3) reflect normal resistance with pressure:flow slopes close to normal. High pressures are then the result of high critical pressures. By contrast, when pulmonary hypertension is associated with extensive loss of the vascular bed due to occlusion or fibrosis, one would predict that the true resistance would be elevated. Then, even small increments of flow would cause major increases in the PA pressure. Data obtained from patients with pulmonary fibrosis studied by the Cleveland group are consistent with this hypothesis.[12]

Patients with left heart disease and more severe pulmonary hypertension appear to be intermediate. Data from the studies of Charms, Brofman and Kohn[13] are plotted in Figure 3. Average values are shown for 10 patients with chronic mitral or left ventricular disease chosen for study because cardiac index before and after obstruction of the right or left pulmonary artery varied by less than 500 ml/min/m^2. Pulmonary hypertension here appears to be due both to an increase in true resistance (steep pressure:flow slope) and to elevated critical pressure (44 mm Hg), and is not due to elevation of left heart pressures which averaged 25.6 mm Hg. Calculation of the pressure:flow ratio without knowledge of this critical pressure would not distinguish between these groups. Further, this ratio would fall as flow rose purely as a consequence of the artifact indicated in Figure 1b.

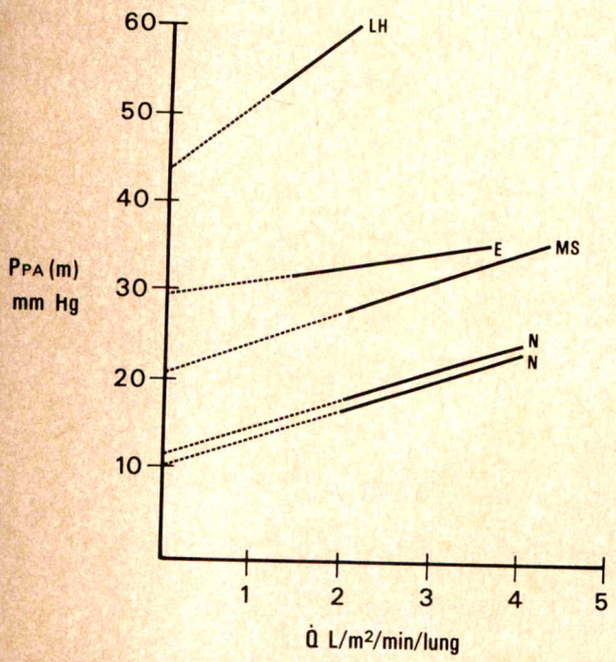

FIGURE 3. Changes of pulmonary artery mean pressure, (P_{PA}(m)) in man before and after flow to 1 lung is increased by obstruction of the opposite pulmonary artery. From data previously reported.[10–13] The **left** and **right** extremity of each **solid line** represents pressure and flow before and after blockage of the opposite pulmonary artery. The **interrupted line** is extrapolated to 0 flow. E = average values from 10 patients with chronic bronchitis and emphysema[11]; LH = average values from 10 patients with left heart disease[12]; MS = average values from 4 patients with mitral stenosis[11]; and N = average values from 6 and 4 normal subjects.[11,10]

Thus, the common practice of calculating so-called resistance using the LA pressure instead of the critical pressure can easily lead to false interpretation of data. In the normal lung, this artifact may be small, but the higher the critical pressure, the greater the artifact produced by ignoring it. In patients with pulmonary hypertension due to lung disease, for example (Fig. 3), this artifact may be extremely large. Here, an intervention which had merely caused a rise in cardiac output would *seem* to have induced vasodilation. Thus, in the absence of knowledge of the slope of the pressure:flow relation, vasodilation can only be concluded to have taken place when a decrease in pressure is observed in the absence of a decrease in flow, or when there is an increase in flow that is not accompanied by an increase in pressure. Failure to recognize this limitation of the pressure:flow ratio can lead to false interpretations in trials of vasodilator drugs in pulmonary hypertension.

In summary, the ratio of PA pressure with or without subtraction of LA pressure, divided by flow, has traditionally been understood to indicate resistance. This is misleading because this ratio will change with changes in flow, without there being any change in the forces opposing flow. To avoid confusion, we suggest that this ratio should be referred to as the pulmonary "pressure:flow ratio." The term PVR should only be used when the correct downstream pressure is known or to describe the slope of the pressure flow plot. PVR, as so defined, is nearly constant over the normal operating range of pressure and flow and does not decrease significantly as pressure and flow increase. The pulmonary circuit can accept high flows without developing high pressures because the resistance of this circuit is low—in normal man, about 1.6 mm Hg/liters/min/m^2.

Systemic Hypertension, Diuretic Drugs, Arrhythmias and Death

PAUL K. WHELTON, MD, MSc

Epidemiologic studies have repeatedly shown a strong relation between level of blood pressure (BP) and risk of disease and death.[1–3] Risk increases in a curvilinear fashion with progressively higher levels of BP, and there is little evidence of a threshold for BP-related cardiovascular complications. Those with the greatest potential for benefit from antihypertensive therapy are those with BPs in the higher end of the distribution. If therapy is confined to this group of hypertensive patients, however, the burden imposed on society by high BP cannot be substantially reduced.[3] Any meaningful attempt to decrease the number of BP-related complications mandates treatment of the much larger number of persons exposed to only a slight increase in BP and associated risk. Special care to recognize and prevent adverse effects resulting from therapy of such persons is essential.

Given the lifelong nature of antihypertensive treatment and the large percentage of hypertensive patients receiving diuretic drugs,[4] even a slight tendency of thiazides to produce laboratory abnormalities would result in a huge number of patient-years of exposure to the potential risks of such changes. Thus, even a risk that is imperceptible to individual physicians and patients might result in a serious public-health hazard. The reported prevalence of diuretic-induced laboratory abnormalities varies dramatically, depending on the criteria for case definition and the type, duration and dosage of diuretic therapy, the composition of the study group and whether prevalence is being measured at 1 point (point prevalence) or over an interval in time (period prevalence). Whatever the exact prevalence, diuretic-induced biochemical changes such as hypokalemia and lipid/lipoprotein abnormalities are frequent. A variety of electrocardiographic changes also have been reported. For many years it has been known that hypokalemia, if severe, can be accompanied by prominent U waves, ST-T depression, T-wave inversion and ventricular ectopic beats. The results of recent studies that have used exercise and ambulatory monitoring of the electrocardiogram suggest that diuretic-induced ventricular ectopic activity may be a much more common occurrence than was previously recognized. These results, although still controversial, are supported by evidence from both hospital and population-based studies.[5–8]

The proposition that diuretic-induced ventricular ectopic activity may occasionally take the form of ventricular fibrillation and lead to sudden death is controversial, and discussion of information related to this proposal is often emotionally charged. The eagerly awaited Multiple Risk Factor Intervention Trial analyses published in this issue of the Journal provide the most compelling evidence to date of a link between diuretic administration and sudden death.[9] The data presented are substantial and cannot be ignored. Having said that, it is important to recognize the strengths and weaknesses of the information presented. The size of the data base and the care with which the results were collected and analyzed represent major strengths. However, the fact that diuretic-induced sudden death was not a prior hypothesis and that the findings presented are based on subgroup analyses are important weaknesses. As pointed out by the investigators, such analyses do not make use of the randomized trial design. No matter how carefully the analyses have been adjusted, the possibility of confounding by unrecognized factors of importance cannot be excluded. Thus, the reported findings do not and cannot provide conclusive evidence of a relation between diuretic administration and sudden death.

What should the clinician do in view of these new findings? It is relevant that the recorded mortality rate from systemic hypertension, stroke and coronary heart disease in the United States has declined impressively during the same period that diuretic treatment became increasingly common in the community.[3,10] Given this progressive decline in cardiovascular mortality, there is no need for panic and such a response would be in-

appropriate. However, caution is in order especially in older men, patients with known electrocardiographic abnormalities, and persons who are concurrently being treated with digitalis. Diuretic drugs should be administered at the smallest dose necessary to achieve the desired reduction in BP.[11] Hypokalemia should be prevented or treated with a salt-restricted diet, potassium-sparing agents or potassium chloride supplements. In addition, alternative forms of drug therapy can be considered. If no contraindications exist, β-blocking drugs provide a well-documented alternative for monotherapy of essential hypertension. In selected instances, monotherapy with a centrally active agent, calcium channel-blocking drug or angiotensin-converting enzyme inhibitor may be more desirable. However, none of the nondiuretic alternatives represents a panacea, because each is known to be a potential cause of undesirable symptoms and laboratory alterations. Moreover, none has been evaluated for the possibility of adverse effects as carefully as diuretic drugs.

The mandate for investigators is more obvious. We need additional information that will confirm or refute the relation between diuretic administration and ventricular ectopic activity. Likewise, clarification of the risk factors and underlying mechanism for any such relation will provide clinicians with a firm basis for prevention and treatment. The hypothesis that a relation exists between diuretic administration and sudden death in certain hypertensive patients with electrocardiographic abnormalities must be explored further. Information from the British Medical Research Council Trial of treatment in mild to moderate hypertension may be informative.[12] Similarly, the ongoing antihypertensive treatment trials of elderly persons may provide valuable information. Unfortunately, the selective nature and sample size of some of these trials may preclude performance of analyses with adequate statistical power. This is not an argument against obtaining the information, but clinicians should be aware that their decisions in this controversial area may have to be based on incomplete data. The best hypothesis test would be provided by a comparison of total and sudden death rates during randomly assigned placebo, diuretic and active nondiuretic treatment of a large group of patients with essential hypertension with and without resting electrocardiographic abnormalities. Unfortunately, financial and practical considerations make the performance of a suitably designed trial of adequate size infeasible.

Coronary Artery Spasm in Hypothyroidism

WILLIAM E. LAWSON, MD
MARCIS T. SODUMS, MD
LLOYD LENSE, MD
PETER F. COHN, MD

A previous report by Wei et al[1] documented coronary spasm possibly caused by hyperthyroidism. It was speculated that an increase in the number of α receptors secondary to hyperthyroidism may render the coronary arteries more vulnerable to spasm when transient increases in parasympathetic tone with attendant postganglionic catecholamine release occurred. The present report of coronary spasm occurring in a patient with hypothroidism is the first described association of these conditions. The demonstration that spasm may be seen with either hyper- or hypothyroidism suggests that the connection of coronary spasm with thyroid dysfunction may be more tenuous and variable than previously postulated.

A 44-year-old man who drank 1 quart of beer and danced on December 31, 1983, suddenly had severe dull retrosternal and left precordial chest pressure radiating to the left arm with accompanying dyspnea, weakness and vomiting. Examination revealed a systolic systemic blood pressure of 90 mm Hg, and an electrocardiogram (ECG) showed supraventricular tachycardia at 160 beats/min with anterolateral subendocardial ischemia. The patient gave a history of hyperthyroidism treated with radioactive iodine 6 years earlier. He had had no interim symptoms suggestive of either hyper- or hypothyroidism and appeared clinically euthyroid. The patient had no risk factors for atherosclerotic heart disease. In the emergency room the patient responded to treatment with morphine, fluids and dopamine, with conversion to normal sinus rhythm and resolution of hypotension. The repeat ECG was remarkable for minor nonspecific ST-T changes. The patient was given timolol, 10 mg twice a day, and a 5-mg nitroglycerin patch; cardiac catheterization was scheduled. Serial cardiac enzyme measurements revealed a modest, persistent elevation in creatine kinase levels that was noncardiac.

During cardiac catheterization on January 6, 1984, while the left coronary catheter in the aorta was being filled with contrast material, the patient complained of severe angina. The ECG showed transmural inferior wall ischemia (Fig. 1). Immediate infusion of contrast medium into the left coronary artery revealed no obstructive lesions. Treatment with atropine, nitroglycerin and Demerol® lessened the chest pressure within several minutes. Selective coronary angiography, performed within 10 minutes of the onset of chest pressure, revealed normal left and dominant right coronary arteries. The right anterior oblique ventriculogram showed akinesia of the posterobasal and inferior left ventricular wall segments and otherwise normal function. By the end of the catheterization, the ECG had reverted to baseline levels (Fig. 2), and subsequent serial cardiac enzyme levels were normal. Thyroid function tests from admission returned and revealed T_3RIA of 61 (80 to 220 ng/dl), T_4 of 3.6 (5.5 to 11.5 ng/dl) and a TSH of 50 (<9.0 mμ/ml). Timolol administration was discontinued and the patient was given nifedipine and synthroid. There has been no evidence of recurrent coronary artery spasm.

Coronary artery spasm may be mediated both by local factors, such as release of vasoactive prostaglandins and by more generalized disturbances, such as an increase

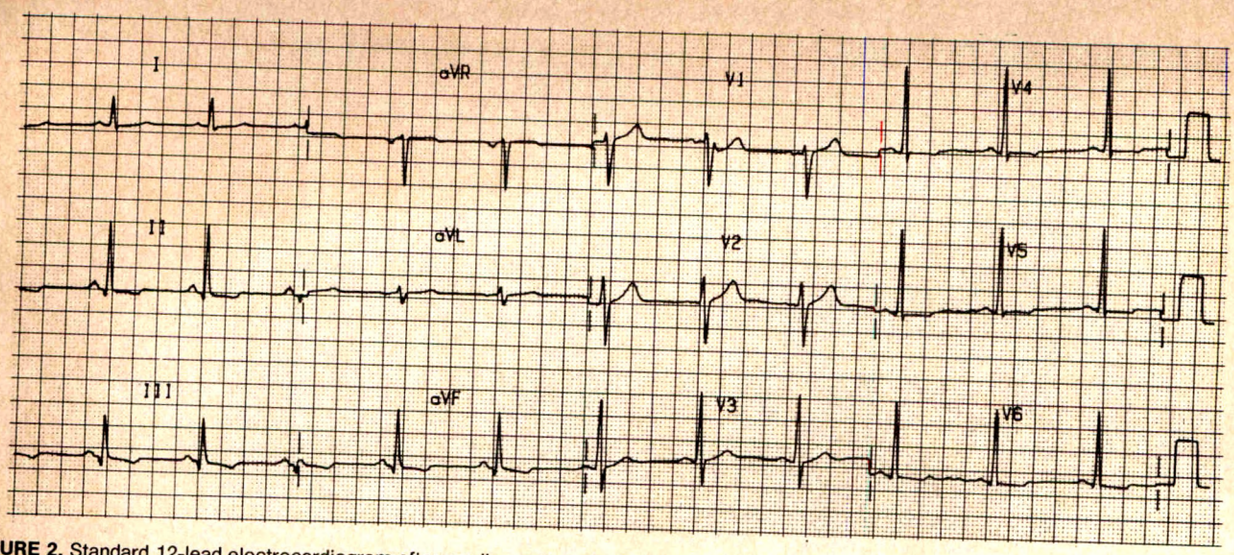

FIGURE 2. Standard 12-lead electrocardiogram after cardiac catheterization.

in circulating catecholamines or autonomic nervous system dysfunction. Advances in our understanding of adrenergic receptor physiology in normal and abnormal states may be applicable to our present case.[2]

An increase in sympathetic nervous system activity or in catecholamine levels results in downregulation with a decrease in β-adrenergic receptor density. Decreased sympathetic activity and low catecholamine levels results in upregulation with an increase in β-receptor density. However, catecholamine levels are not clearly altered with thyroid dysfunction. Beta-adrenergic receptor density increases in hyperthyroidism, which may explain the clinical appearance of increased sympathetic activity. In the hypothyroid patient, both α- and β-adrenergic receptor densities are diminished. The lack of thyroid hormone also affects the coupling of the β receptor with adenylate cyclase causing further functional impairment in the ability to respond to β-adrenergic stimulation. These effects may explain the bradycardia and decreased sympathetic responsiveness seen in hypothyroid patients. In some hypothyroid patients, the lessened ability to respond to β-adrenergic stimulation may render the coronary arteries more susceptible to vasospasm from unopposed α-adrenergic action.

Thallium-201 Exercise Scintigraphy and Left Bundle Branch Block

SIMON H. BRAAT, MD
PEDRO BRUGADA, MD
FRITS W. BÄR, MD
ANTON P. M. GORGELS, MD
HEIN J. J. WELLENS, MD

Results from several centers have shown that the sensitivity and specificity of exercise thallium-201 (Tl-201) myocardial imaging for detecting myocardial ischemia are superior to those of conventional exercise electrocardiography.[1–6] However, the value of Tl-201 myocardial imaging depends on patient selection, acquisition technique and mode (quantitative interpretation) of images. In patients with normal intraventricular conduction, sensitivity and specificity of Tl-201 exercise myocardial imaging has been reported as 85 to 90%, compared with 65 to 70% for exercise electrocardiography alone.[7] Limited information is available about the value of Tl-201 myocardial imaging in patients with left bundle branch block (LBBB). McGowan et al[8] examined 27 patients with LBBB using potassium-43 or rubidium-81 to exclude coronary artery disease (CAD). Hirzel et al[9] examined 19 patients by Tl-201 scintigraphy and coronary angiography for the same purpose. Both studies found a decreased septal uptake of the radionuclide, suggesting a narrowed left anterior descending coronary artery. However, most patients who had a septal defect had a normal left anterior descending coronary artery by coronary angiography.

From the Department of Cardiology, Annadal Hospital, P.O. Box 1918, 6201 BX Maastricht, The Netherlands. Manuscript received July 25, 1984; revised manuscript received August 31, 1984, accepted September 4, 1984.

To further assess the value of Tl-201 myocardial imaging in patients with LBBB and chest pain and to study its relation to CAD, the present study was undertaken in 24 patients with LBBB admitted to the hospital because of chest pain.

Twenty-four patients (8 women, 16 men), aged 35 to 74 years (mean 54), were studied using Tl-201 stress scintigraphy and coronary arteriography. All patients had chest pains suggestive of CAD. No patient had a history of myocardial infarction.

Thirteen patients had systemic hypertension and 4 patients valvular heart disease: 2 mitral reguritation, 1 patient combined mitral stenosis and regurgitation and 1 mitral and aortic regurgitation. Myocardial imaging using an intravenous bolus of 1.5 mCi of thallium chloride was performed during symptom-limited exercise on a bicycle ergometer and repeated after 4 hours. Scintigrams were obtained in the 45° left anterior oblique, anterior and left lateral projections for 6 minutes using a Philips camera with a parallel-hole, all-purpose collimator interfaced to a Philips minicomputer. Images were acquired at 80 keV with 20% window and recorded with a Polaroid® camera and by computer. Both images were analyzed by 2 independent observers unaware of the coronary artery anatomy. Differences were discussed until consensus was obtained. Coronary arteriography was performed using the Judkins technique. CAD was defined as a stenosis greater than 70%. The angiograms were interpreted by 2 experienced observers and disagreement was resolved by consensus by remeasuring stenoses manually.

In 15 patients at least 1 reversible defect was observed (Table I). In 4 patients the defect was located both in the anterior and inferior walls, in 8 patients, in the inferior wall only, and in 3 patients in the anterior wall only. In 9 patients no defect developed on exercise.

***Coronary arteriography:** Eight patients had no significant stenosis of a coronary artery. Five patients had significant stenoses in all 3 coronary arteries. In 5 patients 2-vessel CAD was found: 3 had left anterior descending and left circumflex narrowing and 2 left anterior descending and right CAD. In 6 patients 1-vessel CAD was present: 4 had right, 1 left anterior descending and 1 left circumflex CAD.*

***Correlation between thallium-201 scintigraphy and coronary arteriography:** In 14 of the 16 patients with at least 1 significant coronary narrowing, a reversible defect was noted on Tl-201 scintigraphy. A false-negative scintigraphic response was found in 2 patients. One had 1-vessel CAD (right coronary artery) and the other had significant narrowing in the left anterior descending and the left circumflex coronary arteries. Among the 8 patients with normal coronary arteries, 1 patient had a reversible defect in the septal area. Sensitivity, specificity and predictive accuracy of Tl-201 scintigraphy in our patients were 88%, 86% and 87%, respectively.*

TABLE I Findings in the 24 Patients

Pt	Tl-201 Defect	Coronary Angiogram	Other Disease
1	Ant + inf	3-vessel	Hyp
2	Ant + inf	R + LAD	Hyp
3	Absent	Normal	Hyp
4	Inf	3-vessel	
5	Inf + ant	3-vessel	MR
6	Absent	Normal	
7	Ant	Normal	
8	Ant	LAD	
9	Absent	Normal	
10	Inf + ant	LAD + LC	Hyp
11	Absent	R	Hyp
12	Absent	Normal	Hyp
13	Ant	LAD + LC	Hyp
14	Inf	3 vessel	Hyp
15	Absent	Normal	
16	Absent	Normal	
17	Absent	LAD + LC	Hyp
18	Inf	R + LAD	Hyp
19	Inf	LC	Hyp
20	Inf	R	Hyp
21	Inf	3-vessel	Hyp
22	Inf	R	MR
23	Inf	R	MR + AR
24	Absent	Normal	MR + MS

Ant = anterior; AR = aortic regurgitation; Hyp = hypertension; inf = inferior; LAD = left anterior descending coronary artery; LC = left circumflex coronary artery; MR = mitral regurgitation; MS = mitral stenosis; R = right coronary artery.

The left bundle usually arises as a broad sheet of fibers from the bundle of His to the left side of the muscular ventricular septum, but its anatomy is variable.[10] The anterior half of the left bundle has a dual blood supply in 50% of patients through the atrioventricular (AV) nodal artery from the right coronary artery and from the septal branch from the left anterior descending coronary artery.[11] In 40% of patients, the septal branch is the only blood supply and in 10% the AV nodal artery is the only supply. In 50% of patients the posterior half of the left bundle receives its blood supply from the AV nodal artery. A dual blood supply by the AV nodal and septal branch arteries is present in 40% and in 10% perfusion is by the septal branch alone. Therefore, in a large proportion of patients, the anterior and posterior half of the left bundle has a dual blood supply. Lie et al[12] reported a high incidence of LBBB in patients with inferior wall infarction, suggesting that frequently the mainstem of the left bundle was perfused by the right coronary artery.

Because the left bundle has a dual blood supply in 50% of patients, one would expect 2 defects in these patients, in the septal and in the inferior area on Tl-201 exercise scintigrams, when the cause of the LBBB is ischemic. Two defects were seen in 4 patients. All 4 had significant stenoses in at least 2 coronary arteries. A reversible inferior wall defect alone was seen in 11 patients. They all had at least 1 significant coronary artery narrowing. These observations suggest ischemia as the cause of LBBB in at least 4 patients, although the possibility that the LBBB was caused by systemic hypertension cannot be excluded.

In this study only 1 patient with no significant coronary narrowing showed a reversible septal perfusion defect.

The disparity between the results of our study and that of McGowan et al[8] can be explained by different imaging agents: They used potassium and rubidium-81.

Hirzel et al[9] used Tl-201. Among 19 patients with a history suggestive of CAD, 15 had normal coronary arteries, although all showed a septal defect on Tl-201 scintigraphy. Rowe et al[13] found a defect on Tl-201 scintigraphy in the inferior wall in 2 of 6 patients with CAD and in 4 of 7 patients with normal coronary arteries. They concluded that defects in the inferior wall were seen only in patients with CAD. Our results

also indicated that the area of ischemia in patients with LBBB and CAD was usually located inferoposteriorly.

In 12 of our 15 patients with Tl-201 defects and CAD, the location was inferoposterior, compared with 7 in the anterior area, while 1 of the 3 patients with a single septal defect had normal coronary arteries. Thallium-201 exercise scintigraphy was valuable for detection of CAD in patients with LBBB, who present with angina pectoris. In most patients the area of ischemia is located only inferoposteriorly or is accompanied by a septal defect.

Effects of Noncaptured Stimuli During Rapid Right Ventricular Pacing: Does Concealed Conduction Occur in the Human Ventricle?

WILLIAM G. STEVENSON, MD
ISAAC WIENER, MD

Concealed conduction was defined by Langendorf[1] as "the effect of a non-propagated impulse upon conduction of a subsequently propagated impulse." Subsequently, examples of concealed conduction have been described occurring in the atrioventricular node, His-Purkinje system and bundle branches.[2,3] In 1978, Sung et al,[4] using rapid atrial pacing, demonstrated concealed conduction of noncaptured stimuli in the human atrium. In an attempt to demonstrate this type of conduction in the human ventricle, we applied Sung's method to 18 patients undergoing electrophysiologic study.

Electrophysiologic studies were performed in the postabsorptive state in the absence of antiarrhythmic drugs. The His bundle electrogram was recorded with a 6Fr tripolar catheter positioned across the tricuspid valve. Pacing was performed using a 6Fr quadripolar catheter with 10-mm interelectrode distances positioned in the right ventricular apex. Three patients also had pacing performed from the right ventricular outflow tract, and 3 patients had left ventricular pacing. Pacing was performed using a Medtronic 5325 stimulator that delivers a 2-ms square-wave impulse. Pacing was performed at twice diastolic threshold. The distal electrode pair was used as the cathode (distal) and anode; a ventricular electrogram was recorded from the proximal electrode pair. Surface electrocardiographic leads I, II and III and bipolar intracardiac electrograms were recorded on an Electronics for Medicine DR-16 multichannel recorder at a paper speed of 100 mm/s and filtered from 30 to 500 Hz. Bursts of ventricular pacing at progressively faster rates were performed until 2:1 ventricular capture occurred. The pacing cycle length was then doubled. The time from stimulus artifact (S) to the ventricular electrogram recorded from the proximal electrodes of the pacing catheter (V_{RV}) and the His catheter (V_{His}) was measured at both pacing rates.

Five patients were studied because of resuscitation from cardiac arrest, 4 because of ventricular tachycardia, 4 because of unexplained syncope, 3 because of atrioventricular block, 1 patient because of atrial tachycardia and 1 because of Wolff-Parkinson-White syndrome. Six patients had coronary artery disease, 2 had dilated cardiomyopathy and 10 had no known structural heart disease.

In the 18 patients and 24 sites studied, 2:1 ventricular capture developed at a mean cycle length of 232 ± 23 ms. The mean S-V_{RV} was 53 ± 17 ms and S-V_{His} was 92 ± 22 ms during 2:1 capture. During 1:1 capture at a mean cycle length of 462 ± 46 ms, the mean S-V_{RV} was 52 ± 17 ms and S-V_{His} was 91 ± 22 ms (difference not significant). In no patient was there more than a 5-ms change in conduction time as measured from S to V_{RV}, S to V_{His} or V_{RV} to V_{His} comparing 2:1 ventricular capture to 1:1 capture. Figure 1 illustrates the findings during 2:1 and 1:1 ventricular capture in 1 patient. There were no arrhythmias induced by pacing at rates with 2:1 capture.

Sung attempted to demonstrate concealed conduction in the atrium by incremental atrial pacing to the point of 2:1 capture and then halving the pacing rate, such that the rate at which the atrium was captured remained constant. The time from stimulus artifact to the recording of the high right atrial electrogram, and from high right atrial electrogram to low right atrial electrogram during 1:1 and 2:1 atrial capture were compared.[4] They showed prolongation of intraatrial

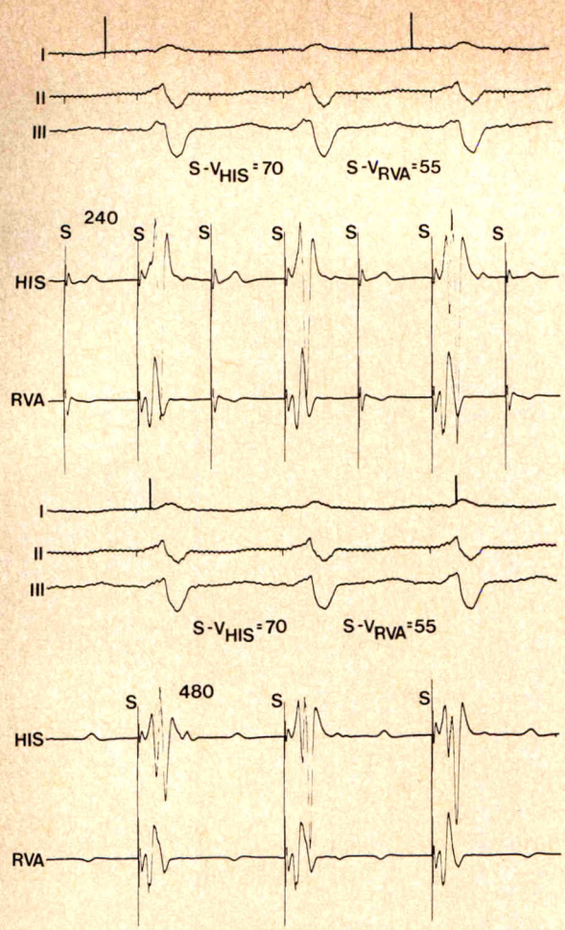

FIGURE 1. Pacing from the right ventricular apex at a cycle length of 240 ms with 2:1 capture (**top**) and 480 ms with 1:1 capture (**bottom**) in the same patient demonstrating no change in S-V_{RV}, S-V_{His} or V_{RV}-V_{His} intervals. Time lines are 1 second.

conduction times of 15 ms or longer during 2:1 atrial capture in 12 of 35 patients. All 12 had evidence of atrial disease manifested as sick sinus syndrome, "chronic conduction system disease," paroxysmal supraventricular tachycardia, or atrial flutter or fibrillation. Sung suggested that during 2:1 atrial capture, the nonpropagated stimulus partially penetrated the atrium (concealed conduction), delaying conduction of the subsequent stimulus.

We could not demonstrate this phenomenon in the human ventricle. We used the same pacing technique, and 2:1 capture occurred over an overlapping range of pacing cycle lengths (200 to 290 ms in the ventricle vs 150 to 260 ms in the atrium). Our failure to demonstrate concealed conduction in the ventricle may relate to differences in the electrophysiologic properties of human atria and ventricles. Sung's patients had a variety of conduction abnormalities or spontaneous atrial arrhythmias. Hordof et al[5] studied atrial fibers from such patients and demonstrated diminished resting potentials and slow action potential upstrokes, features that are associated with slow conduction velocity and calcium dependency. However, these abnormalities, which result in recurrent atrial arrhythmias, may be incompatible with survival when found in the ventricle, and may have been absent in our patients. Moreover, Spach and Kootsey[6] showed that marked slowing of conduction can occur in normal atrial tissue because of impulse propagation perpendicular to the long axis of atrial fibers. This transverse conduction has a greater safety factor than longitudinal conduction and can therefore be seen during premature stimulation.

Polymorphic Ventricular Tachycardia and Ventricular Fibrillation Due to N-Acetyl Procainamide

JOHN M. HERRE, MD
JAMES A. THOMPSON, MD

Worsening of ventricular arrhythmias has been reported during therapy with class I antiarrhythmic agents.[1] N-acetyl procainamide (NAPA), the first metabolite of procainamide, has been implicated as a cause of polymorphic nonsustained ventricular tachycardia (VT) in 1 patient.[2] Sudden death has occurred during NAPA therapy, but recurrent ventricular fibrillation (VF) resulting from NAPA treatment alone has not been documented previously.[3,4] The following case demonstrates this phenomenon.

A 66-year-old man was admitted to the hospital for elective right hemicolectomy. He had had acute myocardial infarctions at ages 60 and 62 years, but neither angina pectoris nor symptoms of heart failure subsequently. At admission, he was taking quinidine sulfate (1,200 mg/day) for control of ventricular premature complexes (VPCs) and asymptomatic nonsustained ventricular tachycardia (VT). He had been undergoing chronic hemodialysis since age 63 years (1981) because of hypertensive renal failure.

Quinidine treatment was stopped at surgery. On the fifth postoperative day, multiform VPCs and nonsustained VT

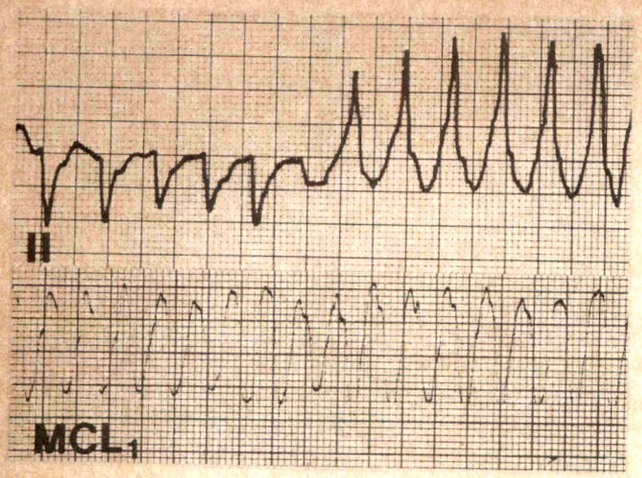

FIGURE 1. Top, polymorphic ventricular tachycardia before discontinuation of procainamide. **Bottom,** recurrent ventricular tachycardia 9 days after procainamide was discontinued (procainamide level <1.0 mg/liter). II = electrocardiographic lead II; MCL = modified clavicular lead I.

(to 5 beats) were noted. Lidocaine was ineffective and intravenous procainamide therapy was begun and the dose was increased to 4 mg/min. On the eleventh postoperative day, the patient had a seizure and was treated with phenytoin. On the twelfth postoperative day, he again had a seizure. The electrocardiogram demonstrated both polymorphic nonsustained VT (Fig. 1) and VF requiring cardioversion. The corrected QT interval after cardioversion was 700 ms. The procainamide level was 21 mg/liter and the NAPA level was 52 mg/liter. Procainamide therapy was discontinued. No other causes for VT/VF were delineated. The left ventricular ejection fraction was 39% by multiple-gated blood pool scan. Polymorphic VT and VF recurred 9 hours later. Atrial pacing was instituted at 110 pulses/min and increased to 140 pulses/min before resulting in complete suppression of the arrhythmia. Hemodialysis was performed daily for 4 days in an effort to remove NAPA. Pacing was continued for 2 days, by which time the procainamide level had decreased to 4.6 mg/liter. Eleven seconds after discontinuation of pacing, VT/VF recurred. After cardioversion, atrial pacing was reinstituted. Eight days after procainamide therapy was discontinued, procainamide was undetectable in serum despite a NAPA level of 15 mg/liter. Pacing was discontinued the next day. VT/VF recurred 90 minutes later (Fig. 1), at a time when procainamide was undetectable and the NAPA level was 12 mg/liter.

Pacing was reinstituted and continued for 5 more days. Procainamide remained undetectable and the NAPA level had decreased to 4.3 mg/liter. No further polymorphic VT or VF was noted after pacing was discontinued. The patient continued to have multiform VPCs and nonsustained VT. Figure 2 is a summary of the relation between drug levels and VT/VF.

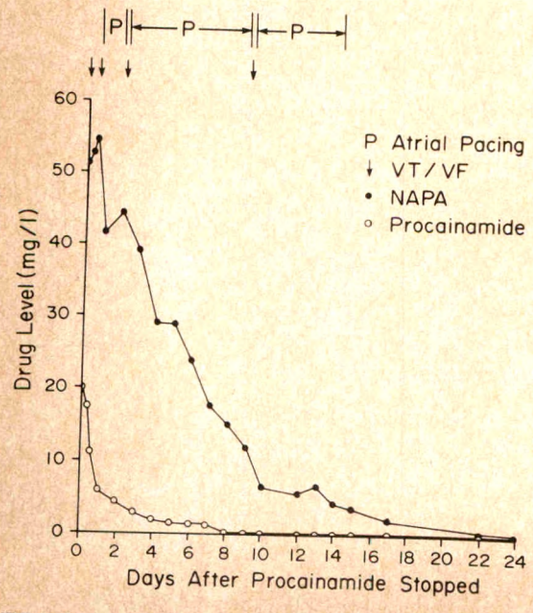

FIGURE 2. Occurrence of ventricular tachycardia/ventricular fibrillation (VT/VF) with decreasing procainamide and N-acetyl procainamide (NAPA) levels and prevention of VT/VF by atrial pacing.

NAPA has antiarrhythmic efficacy independent of its parent drug. The therapeutic range appears to be 10 to 24 mg/liter.[5] Kluger et al[3] reported sudden death in 4 of 19 patients receiving NAPA, but concluded that sudden death represented lack of efficacy rather than worsening of the arrhythmia. Winkle et al[4] reported sudden death in 1 of 11 patients receiving NAPA, but could not prove that NAPA contributed to the death. Olshansky et al[2] reported recurrent polymorphic nonsustained VT without VF in a patient with NAPA levels between 29 and 33 mg/liter, at a time when procainamide levels were as low as 4.1 mg/liter. This report suggested that high NAPA levels could lead to VT but VF was not observed.

In our patient, the first 3 episodes of polymorphic VT and VF could be attributed, at least in part, to procainamide. However, the fourth episode occurred at the time when procainamide had been undetectable in plasma for more than 24 hours. Although polymorphic VT and VF may be seen in a number of disease states, including coronary artery disease,[1] the first appearance of these arrhythmias after the addition of a new drug and the disappearance after adequate washout of the drug is suggestive of a proarrhythmic effect.

The findings in this patient confirm that therapeutic or toxic NAPA levels can cause recurrent VT/VF in sensitive patients, particularly in the setting of chronic renal failure, in which the accumulation of NAPA is well documented.[6] Although hemodialysis is of limited value in the management of NAPA toxicity, overdrive pacing may be lifesaving during the long period required for elimination of NAPA in patients undergoing dialysis.

Prosthetic Mitral Regurgitation Detected by Doppler Echocardiography

ROBERT P. FERRARA, MD
ARTHUR J. LABOVITZ, MD
ROBERT D. WIENS, MD
HAROLD L. KENNEDY, MD
GEORGE A. WILLIAMS, MD

Doppler echocardiography is a useful means of evaluating cardiac valve function noninvasively.[1,2] The detection of mitral regurgitation (MR) by Doppler techniques has shown high sensitivity and specificity when correlated to the degree of MR determined by contrast ventriculography.[1] However, assessment of prosthetic MR with Doppler echocardiography is more difficult than detection of native valve MR, especially when the tilting disc prosthetic valve has been evaluated, because of difficulty in obtaining Doppler signals from behind the prosthesis.[3] We describe a patient with paravalvular MR around a dehiscent Björk-Shiley mitral prosthesis in which the regurgitant jet was easily detected by Doppler, and the calculated mitral valve orifice increased.

A 64-year-old woman, who had a mitral commissurotomy at age 52 years for mitral stenosis, was doing well until age 62 years (June 1982) when severe dyspnea on exertion developed and she underwent replacement of the stenotic mitral valve with a Björk-Shiley prosthesis. She did well until November 1982, when she had severe congestive heart failure associated with a loud MR murmur. Evaluation revealed S. epidermidis *endocarditis. Abnormal rocking motion of the stent and marked paravalvular leakage was confirmed at cardiac catheterization. A new Björk-Shiley mitral prosthesis was implanted and she received 6 weeks of intravenous vancomycin and rifampin. At the time of discharge, 2-dimensional (2-D) and Doppler echocardiograms documented normal prosthetic valve function, normal flow characteristics across the prosthesis and no MR (Fig. 1, left). She was readmitted 2 weeks later with symptoms of mild congestive heart failure, at which time a soft apical systolic murmur was heard. Two-dimensional echocardiography showed unobstructed valve motion without abnormal stent motion and was unchanged from the previous study. The Doppler examination, however, revealed new regurgitant flow across the prosthetic valve, increased diastolic velocity, and increased mitral valve orifice from 2.0 to 2.2 cm^2 as calculated by the pressure-half time method[2] (Fig. 1, right). Congestive heart failure progressed. Repeat 2-D echocardiography revealed increased systolic motion of the stent (Fig. 2), and the corresponding Doppler study showed regurgitant mitral flow and a further increased mitral valve orifice (2.7 cm^2). Cardiac catheterization confirmed marked paravalvular leakage through the posteromedial aspect of the prosthesis. At surgery the valve was dehisced in its medial aspect. The valve ring was resutured, but the patient died during operation.*

M-mode and 2-D echocardiographic evaluation of mechanical prosthetic valves provides qualitative, but not quantitative, information regarding valve function,[4] and has low sensitivity in detecting paravalvular leak, relying on associated findings such as hyperdynamic left ventricle and septum. Doppler echocardiography correlates well with invasive means in the quantitative evaluation of regurgitant and stenotic native valves.[1–3] Although assessment of regurgitant flow behind a tilting disc prosthesis is difficult, Doppler examination was recently shown to be a sensitive means of detecting prosthetic MR in patients in whom systolic murmurs were heard after valve replacement regardless of the presence or absence of prosthetic MR.[5]

Two interesting features are demonstrated. First, the Doppler evidence for prosthetic MR was present 2

From the Division of Cardiology, St. Louis University School of Medicine, 1325 South Grand Boulevard, St. Louis, Missouri 63104. Manuscript received June 22, 1984; revised manuscript received August 23, 1984, accepted August 27, 1984.

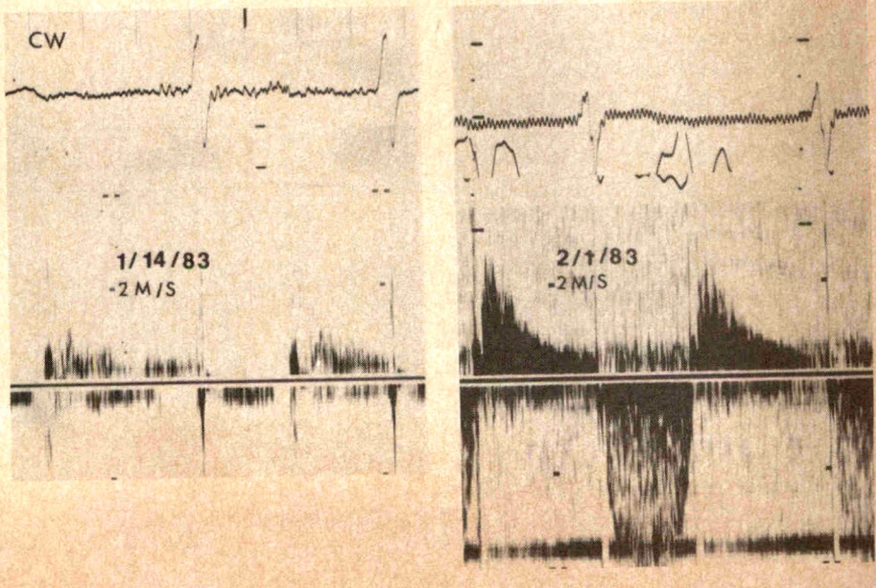

FIGURE 1. Left, apical continuous-wave Doppler tracing of the prosthetic mitral valve before the patient was discharged with a normally functioning prosthesis. Note the low diastolic velocity and absent systolic velocities. **Right,** continuous-wave Doppler tracing of the same valve 2 weeks later. The scale is unchanged. Diastolic velocities have doubled and new systolic velocities are present below the baseline representing new mitral regurgitation. M/S = meters per second.

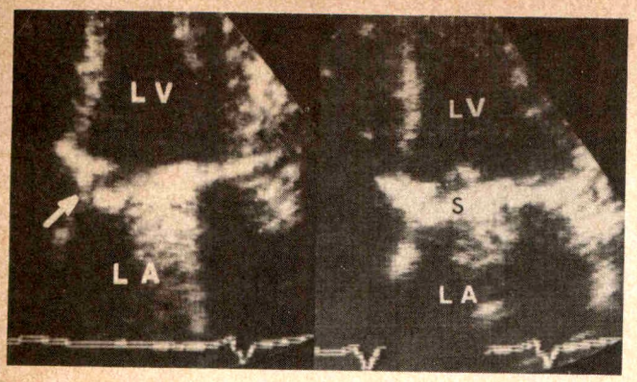

FIGURE 2. Apical view of the mitral prosthesis in systole (**left**) and diastole (**right**) just before the patient's death. Note the clear separation of the valve from the anulus (**arrow**) during systole. LA = left atrium; LV = left ventricle; S = stent.

weeks before the 2-D study revealed abnormal stent motion. Second, in addition to the detection of systolic regurgitant flow, the Doppler study confirmed prosthetic MR by showing a calculated increase in mitral valve area, which is most likely due to diastolic flow around the dehisced stent and through the prosthesis.

Analysis of Doppler flow pattern changes in diastole as well as systole may provide useful information in evaluation of prosthetic mitral valvular dysfunction.

Tissue Characterization by Magnetic Resonance Imaging in Hypertrophic Cardiomyopathy

DONALD FARMER, MD
CHARLES B. HIGGINS, MD
EDWARD YEE, MD
MARTIN J. LIPTON, MD
DENNIS WAHR, MD
THOMAS PORTS, MD

A method for providing tissue characterization of the myocardium has been sought for years. Magnetic resonance imaging (MRI) has demonstrated excellent soft tissue differentiation and has been proposed as a method for tissue characterization. This capability of MRI is suggested from previous studies that showed changes in signal intensity of ischemic compared with normal myocardium in experimental preparations.[1,2] Measurement of magnetic relaxation times, T1 and T2, in animal studies have verified a difference in these times between normal and ischemically damaged myocardium.[1–3] Recently, we encountered a patient with hypertrophic cardiomyopathy (HC) in whom MRI provided more accurate anatomic depiction of the condition than other imaging techniques. MRI also revealed differences in signal intensity at various sites in the left ventricular (LV) myocardium due to fibrosis and myocardial ischemia.

From the Departments of Radiology, Medicine and Surgery, University of California, San Francisco, California 94143. Manuscript received May 23, 1984; revised manuscript received August 16, 1984, accepted August 23, 1984.

A 62-year-old man was admitted for evaluation of refractory recurrent ventricular tachycardia. Cardiac catheterization at age 48 years yielded findings consistent with HC. A subsequent echocardiogram in 1982 showed an LV aneurysm and a prolapsing mitral valve. During the current admission, 2-dimensional echocardiography showed a dyskinetic apex and an extremely hypertrophied proximal portion and midportion of the left ventricle with systolic cavity obliteration. Cardiac angiography was interpreted as asymmetric encroachment of the cardiac walls upon the LV cavity with division of the chamber into a small-volume, hyperdynamic proximal chamber and a distal akinetic chamber. The 2 major cavities were separated by a wide ring of thickened myocardium in the midportion of the ventricle. The proximal and distal cavities were connected by a narrow

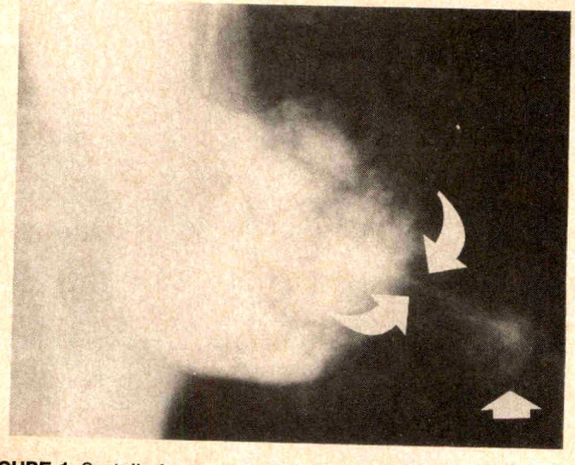

FIGURE 1. Systolic frame of the left ventricular cineangiogram (right anterior oblique projection). There is severe midventricular narrowing producing a small channel (**arrows**), which leads into a small akinetic apical chamber (**arrowhead**).

tunnel coursing through the ring of hypertrophied muscle (Fig. 1). A rare form of HC of the midventricular type was considered, although a cardiac tumor causing the segmentation could not be excluded. The coronary arteriogram revealed no fixed obstruction lesions, but did reveal severe systolic narrowing of an intramyocardial left anterior descending coronary artery.

MRI was performed with a 0.35-tesla superconductive type (Diasonics, Inc.), which gave a resonance frequency for hydrogen of 15 MHz. The multislice imaging technique was used whereby 5 adjacent but not contiguous 7.0-mm-thick tissue sections (2.5-mm gap between slices) were pulsed at 100-ms intervals during each repetition interval (TR). Thus, the imaging period for all 5 sections was approximately 500 ms. This duty cycle of 500 ms was accommodated within the RR interval for this patient. With this technique, the slices are not in the same phase of the cardiac cycle. The sectional (plane) images were reconstructed with the 2-dimensional Fourier transform technique. The reconstruction matrix comprised 128 vertical and 256 horizontal pixels. It was displayed in 256 gray levels, with the brightest area representing the tissue with the greatest MRI signal intensity. Spatial resolution was 1.6 mm. The TR was determined by the RR interval of the electrocardiogram when gated to every heart beat and double the RR interval when gated to every second heart beat. The echo delay times (TE) were 28 and 56 ms.

Magnetic resonance images showed obliteration of the LV cavity by marked thickening of the anterior, anteroseptal and anterolateral walls of the LV myocardium (Fig. 2). At the midventricular level, only the inflow portion was patent, with an anteriorly situated aneurysmal cavity at the apex, connected only by a narrow channel to the residual inflow cavity. This appearance was similar to that shown by left ventriculography (Fig. 1). In addition to defining the anatomic configuration of the ventricle, the images also demonstrated inhomogeneity of the myocardial signal intensity. The upper septum had normal intensity, whereas the anteroseptal region had low intensity. Additionally, there was a region of high signal intensity involving the subendocardial layer of the apical segment (Fig. 2). There was a greater increase in signal intensity of the apical subendocardial layer on the TE 56-ms image than on the TE 28-ms image. This finding is consistent with a long T2 relaxation time of the subendocardial myocardium. High signal intensity and prolonged T2 time were observed in dogs with acute myocardial infarctions[1,2]; these experimental data were the basis of interpretation of the MR study in this case. The observations in the present case and the prior experimental results suggested that the variability of the signal intensity in the myocardium represented fresh ischemic damage in the high-intensity region, while the low intensity region was fibrosis at the site of remote myocardial ischemia injury. In view of the mass effect on the ventricular cavity, the possibility of a myocardial tumor was also considered. The magnetic resonance images (Fig. 3) also provided evidence of stasis of flow in the narrowed LV cavity. Comparison of first (TE = 28 ms) and record (TE = 56 ms) images showed filling of the chamber with high-intensity signal on the second echo image. This finding is consistent with experimental data indicating that this pattern is consistent with flow stasis.[4]

At surgery, a LV apical aneurysm was resected and the apical scar was plicated. Gross examination of the ventricle during bypass revealed areas of tough, fibrous myocardium adjacent to edematous myocardium in the subendocardial layer of the mass of myocardium that nearly obliterated the midportion and distal portion of the left ventricle. Extreme hypertrophy of the myocardium at the base of the papillary muscles was noted. Pathologic examination of the resected portion of the left ventricle revealed marked interstitial fibrosis separating sparse myocardial fibers. The regions found to be edematous by inspection were not biopsied.

A wide spectrum of distribution of HC exists within the left ventricle.[5,6] While asymmetric septal hypertrophy is the most frequent type, several variations of this disease have been uncovered in the past decade, of which the midventricular type is apparently very rare.[5] MRI provided an accurate anatomic assessment in this

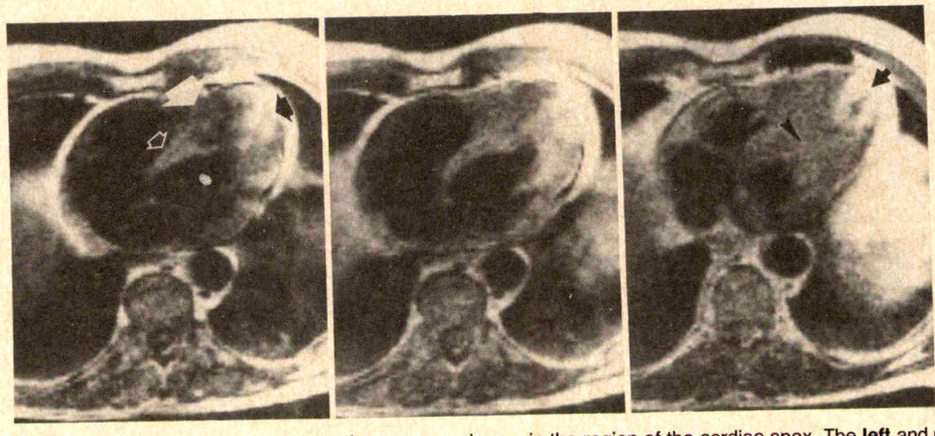

FIGURE 2. Sequential but not contiguous transverse magnetic resonance image in the region of the cardiac apex. The **left** and **middle** panels were produced from the first spin echo (TE = 28 ms); the **right** panel was from the second spin echo (TE = 56 ms). Three areas of signal intensity can be seen within the myocardium (**left**). The upper septum (**open white arrow**) has normal signal intensity, whereas the anteroseptal portion (**white arrow**) shows diminished signal intensity and corresponded to regions of fibrosis at surgery. The region of high signal intensity (**black arrow**) adjacent to the area of anteroseptal fibrosis suggests soft tissue edema secondary to acute myocardial ischemic damage near the apex. In the image on the **right,** which was obtained during ventricular systole, the left ventricular cavity is nearly obliterated in its midportion (**arrowhead**), corresponding to the left ventricular cineangiogram in Figure 1. The small akinetic apical chamber (**arrow**) is rimmed by high signal intensity, suggesting subendocardial edema. There are regions of high signal intensity in the anterior myocardium on all images, suggesting that the area of ischemic damage involves a wide region.

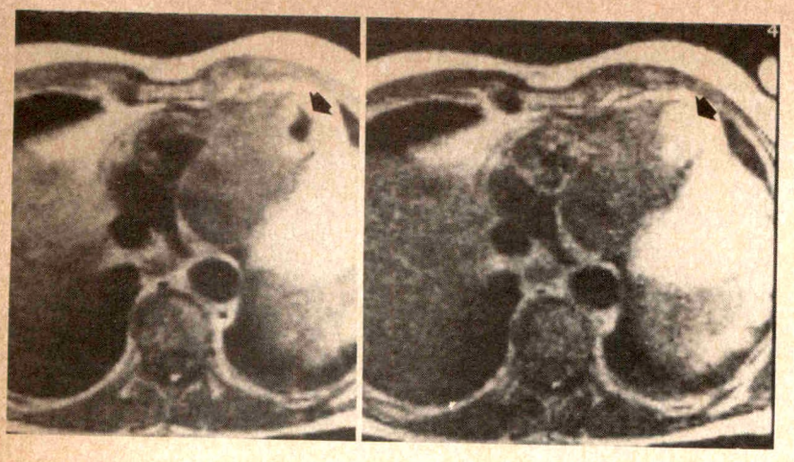

FIGURE 3. Transverse magnetic resonance images at the apical portion of the left ventricle showing obliteration of the inferior portion of the ventricular cavity, leaving only the small akinetic apical chamber. The image produced from the first spin-echo (**left**) (TE = 28 ms) reveals the high-signal intensity rim around the chamber (**arrow**), corresponding to subendocardial edema. In the second spin-echo image (**right**, TE = 56 ms), the chamber is filled with signal secondary to extremely sluggish flow in the akinetic region (**arrowhead**).

unusual case. Previous reports have also indicated that gated MRI provides clear anatomic depiction of cardiac[7] and pericardial abnormalities[8] because it provides high natural contrast between the blood pool and the walls of the heart as a consequence of the virtual absence of magnetic resonance signal from blood flowing at normal velocity.

Perhaps more important in this patient was the variability in myocardial signal intensity, which corresponded to differences in the nature of the tissue in the LV wall. The ability of MRI to discern tissue water content[1,2] and suggest fibrous change in tissues[9] due to alterations in magnetic relaxation times (T1 and T2 times) has been proposed. The current report suggests that this sensitivity to variations in the composition of tissues can provide myocardial tissue characterization in patients.

Origin of the Right Coronary Artery from the Pulmonary Trunk: Diagnosis by Two-Dimensional Echocardiography

CLIFTON WORSHAM, MD
STEPHEN P. SANDERS, MD
BRUNO M. BURGER, MD

Anomalous origin of the right coronary artery (RCA) from the pulmonary trunk (PT) is rare. Fewer than 20 cases have been reported.[1] Most have been incidental findings at autopsy or during surgery for other reasons.[2–4] Rarely, diagnosis has been made by angiography.[5,6] We report here a patient with the RCA from the PT, diagnosed by 2-dimensional echocardiography (2-D echo).

From the Department of Pediatrics, Harvard Medical School, and the Department of Cardiology, The Children's Hospital, Boston, Massachusetts 02115. Dr. Worsham's present affiliation: Cigna Health Plan, Division of Pediatrics, Phoenix, Arizona. Dr. Burger's present affiliation: Centro Medico Docente La Trinidad, Caracas, Venezuela.

Manuscript received August 13, 1984; revised manuscript received August 27, 1984, accepted August 29, 1984.

T.A., a 6.5-year-old asymptomatic girl, was referred because of precordial murmur. Examination disclosed a grade 2/6 blowing midsystolic ejection murmur at the left lower sternal border without radiation. The electrocardiogram showed a QRS axis of +50° without evidence of left ventricular hypertrophy or repolarization abnormalities. The cardiac silouette was minimally enlarged on chest radiograph. A 2-D echocardiogram disclosed a dilated left coronary artery arising from the aorta (Fig. 1A). The right coronary artery, seen in parasternal short-axis view, also was dilated and appeared to course anterior to the aorta to join the PT (Fig. 1B). Doppler examination revealed a diastolic flow disturbance in the PT adjacent to the origin of the RCA. Both ventricles were of normal size and appeared to function normally. Origin of the RCA from the PT was subsequently documented by cineangiography (Fig. 2). A left-to-right shunt (Qp/Qs = 1.4:1) was demonstrated. The end-diastolic pressure was 1 to 4 mm Hg in both ventricles before angiography, but the left ventricular end-diastolic pressure increased to 20 mm Hg after angiography.

Dilatation of the coronary arteries is a distinctive echocardiographic finding that suggests an anomalous

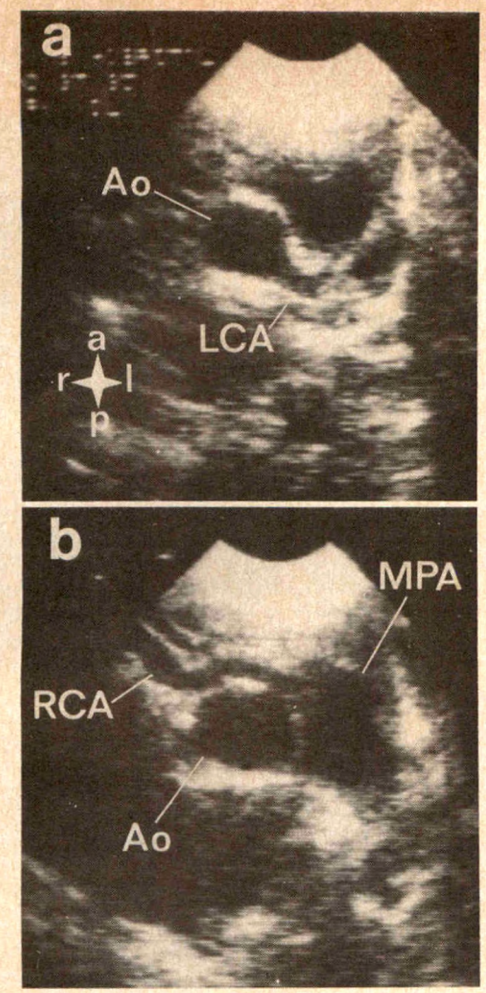

FIGURE 1. a, parasternal short-axis view illustrating the dilated left coronary artery (LCA) connecting with the aorta (Ao). **b,** similar view showing the right coronary artery (RCA) coursing anterior to the aorta to connect with the main pulmonary artery (MPA). a = anterior; l = left; p = posterior; r = right.

origin or fistulous connection of 1 or both coronary arteries.[1] In our patient the left coronary artery was dilated, but it arose from the aorta. The large RCA passed anterior to the aorta to reach the PT. Many planes of examination were used, but no connection between the RCA and the aorta could be demonstrated. Doppler examination confirmed abnormal diastolic flow in the PT.

A prominent conus branch of the RCA may course anterior to the aorta and, due to false dropout, may

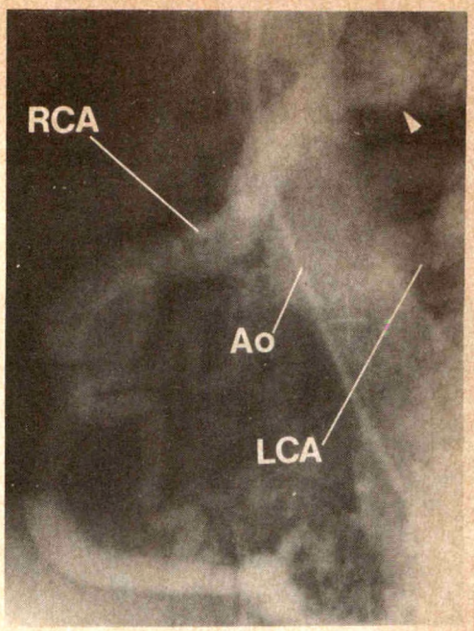

FIGURE 2. Angiogram in left anterior oblique projection showing the anomalous right coronary artery (RCA) passing anterior and to the left of the aorta (Ao) to connect with the main pulmonary artery. A small amount of contrast material can be seen in the main pulmonary artery (**arrow**). LCA = left coronary artery.

appear to connect with the pulmonary artery. Nevertheless, this finding should not be associated with dilatation of the coronary arteries, and careful examination of the right coronary sinus of Valsalva should disclose the origin of the right coronary artery.

The normal left ventricular size at rest and shortening fraction indicates that ventricular size and function are not reliable diagnostic criteria for anomalous origin of a coronary artery.

Abnormal Position of the Brachiocephalic Vein

JEFFREY F. SMALLHORN, MD
PAOLO ZIELINSKY, MD
ROBERT M. FREEDOM, MD
RICHARD D. ROWE, MD

With the advent of suprasternal echocardiography, both normal and abnormal systemic venous drainage can be delineated noninvasively.[1,2] Persistence of the left superior caval vein (SCV) is readily identified and can be differentiated from a left vertical vein in patients with anomalous pulmonary venous connection.[2,3] Similarly, the absence of a bridging brachiocephalic vein (innominate vein) in the presence of a left SCV is reliably recognized.[1] The left brachiocephalic vein invariably runs in front of the aorta to its point of communication with the right-sided brachiocephalic vein. Rarely, the left brachiocephalic vein has a subaortic course running beneath the aortic arch.[4–6] This study describes cross-sectional echocardiographic features in 7 patients in whom the left brachiocephalic vein ran beneath the aortic arch before communicating with the right brachiocephalic vein.

In the normal patient, in the suprasternal long-axis projection, the left brachiocephalic vein can be seen at its point of communication with the right to form the SCV (Fig. 1a). With anticlockwise rotation the azygous vein can be visualized, just above the SCV right atrial junction (Fig. 1b).

Seven patients were identified in whom the brachiocephalic vein ran beneath the aortic arch. In 6 the aortic arch was right-sided. Abnormalities of the right ventricular outflow tract were the most frequent associated anomalies, although in patient 5, the intracardiac anatomy was normal. In patient 1, the central pulmonary arteries were absent, and the left brachiocephalic vein was the only vascular structure beneath the aortic arch (Fig. 2).

The first clue to the presence of an abnormal position of the brachiocephalic vein was seen in the frontal plane projection, where an absence of the vessel anterior to the aortic arch was noted (Fig. 3a). With closer inspection, the vessel could be seen at its origin on the left, then traced inferiorly and to the right beneath the aortic arch (Fig. 3a). It appeared to communicate with the right brachiocephalic vein at a more inferior site, with the resulting SCV being shorter than

This study was supported by Coordena Gao de Aperfeigoamento de Pessoal de Nivel Superior (Capes), Brazil. Manuscript received May 29, 1984; revised manuscript received September 10, 1984, accepted September 11, 1984.

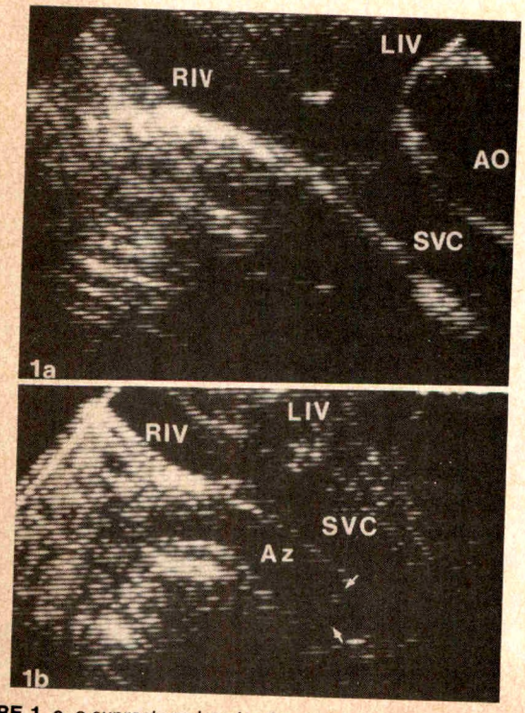

FIGURE 1. a, a suprasternal projection in the patient with a normally positioned left brachiocephalic vein (innominate vein) (LIV). **b,** relation of the azygous (Az) vein to the superior caval vein (SVC). AO = aorta; RIV = right brachiocephalic vein.

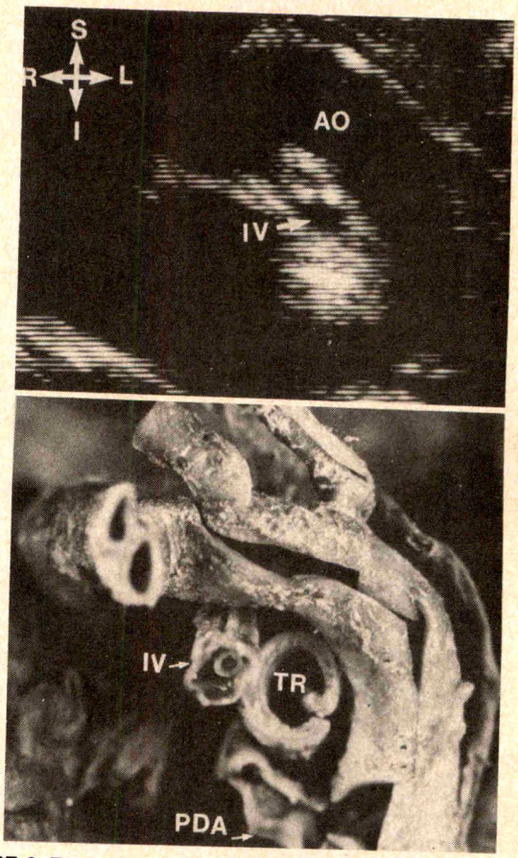

FIGURE 2. Top, suprasternal long-axis projection in patient with an abnormally positioned brachiocephalic vein, pulmonary atresia, ventricular septal defect and absent central pulmonary artery. The only structure seen in the crook of the aortic arch is the left brachiocephalic vein (IV). **Bottom,** anatomic appearance in a different patient. AO = aorta; I = inferior; L = left; PDA = patent ductus arteriosus; R = right; S = superior; TR = trachea.

normal. The azygos vein was situated above the origin of the SCV from the brachiocephalic vein (Fig. 3c), unlike normally, where it lies above the site of entry of the SCV into the right atrium (Fig. 1b). The brachiocephalic vein appeared to run in front of the right pulmonary artery.

In the long-axis projection, in the presence of central pulmonary arteries, the brachiocephalic vein and the pulmonary artery could be seen in their short axis (Fig. 4). In the patient with absent central pulmonary arteries, a solitary vessel was observed (Fig. 2). Confirmation of the abnormality was available in all but patient 5, either at operation or cardiac catheterization. Simultaneous aortic root and brachiocephalic vein angiography demonstrated the abnormality (Fig. 5). Similarly, in 1 patient contrast echocardiography was performed in the left brachiocephalic vein with flow observed beneath the aortic arch (Fig. 3b). The left and right brachiocephalic veins are formed by the confluence of the internal jugular and subclavian veins. The normal left brachiocephalic vein then courses in front of the transverse aortic arch to its site of communication with the right brachiocephalic vein, resulting in the formation of the SCV. The azygos vein arises from the posterolateral aspect of the SCV below the point of communication of the brachiocephalic veins.

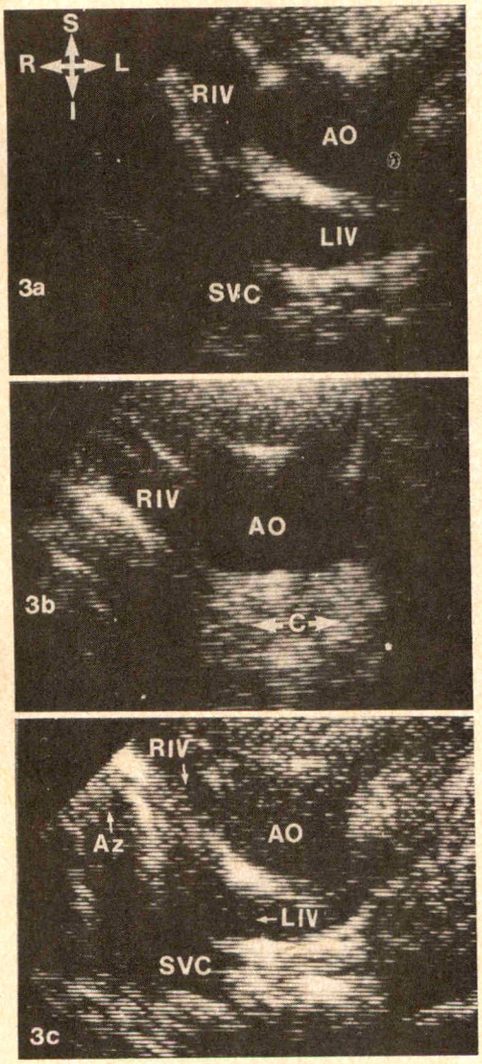

FIGURE 3. a, suprasternal frontal plane projection in a patient with an abnormally positioned left brachiocephalic vein (LIV). Note the absence of a brachiocephalic vein above the ascending aorta (AO). The left brachiocephalic vein runs beneath the aorta before its communication with the right brachiocephalic vein (RIV). Note the resulting short superior caval vein (SVC). **b,** suprasternal frontal plane projection from the same patient after injection of contrast (C) into the left brachiocephalic vein. Note the contrast that opacifies this venous structure, which lies beneath the aortic arch (AO). **c,** a suprasternal frontal plane projection from the same patient demonstrating the azygous (Az) vein which originates from the base of the right brachiocephalic vein (RIV) rather than the superior caval vein (SVC); other abbreviations as in Figures 1 and 2.

Rarely, the left brachiocephalic vein runs inferiorly and to the right beneath the aortic arch, in front of the ligamentum.[4–6] This results in a short SCV with the azygos vein arising from the right brachiocephalic vein, above its site of communication with the left brachiocephalic vein. Approximately 12 cases have been reported.[4–6] Apart from a report of a patient with tetralogy of Fallot with a left aortic arch,[5] the others appear to have been incidental findings in persons with structurally normal hearts.

Previously, 1 case has been described in which suprasternal M-mode echocardiography and contrast studies were performed.[5]

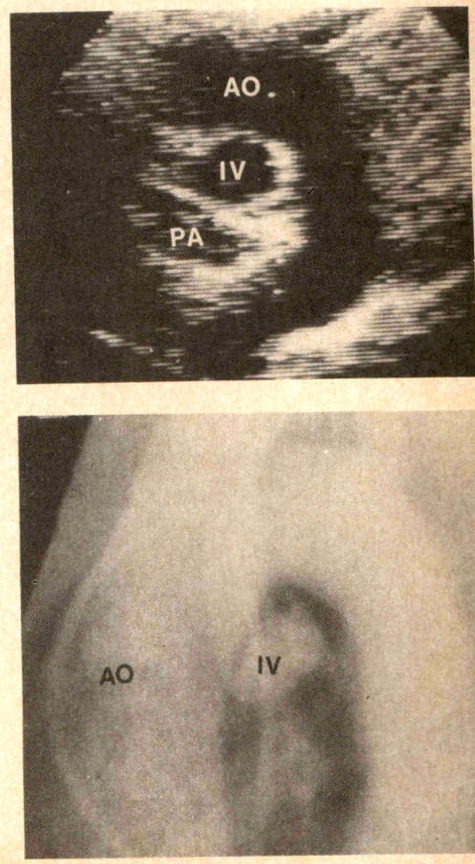

FIGURE 4. Top, a suprasternal long-axis projection in a patient with a left aortic arch, normal sized pulmonary arteries (PA) where the left brachiocephalic vein ran beneath the aortic arch. Note the 2 structures seen beneath the crook of the aortic arch. **Bottom,** angiocardiographic appearance in a different patient. Abbreviations as in Figure 1.

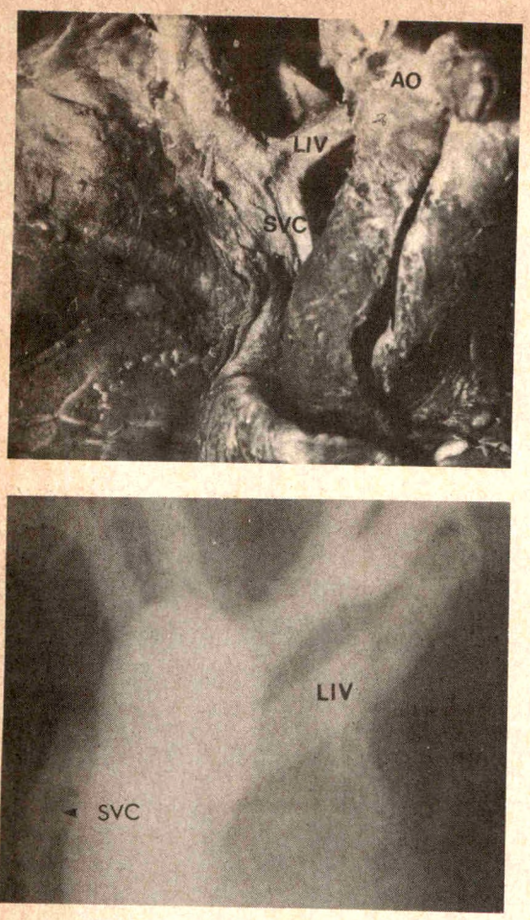

FIGURE 5. Top, anatomic specimen viewed from the front, where the innominate vein runs beneath the aortic arch. This patient also had pulmonary atresia. **Bottom,** simultaneous contrast injection into the aorta and left brachiocephalic vein (LIV).

Systemic venous anomalies are readily identified by cross-sectional echocardiography, particularly the presence of a left SCV and the presence or absence of an associated bridging brachiocephalic vein.[1,2] To our knowledge, this rare anomaly has not previously been described by cross-sectional echocardiography. It is important to differentiate this structure from central pulmonary arteries, particularly in patients with reduced pulmonary flow where they may be absent. If care is not taken, this vessel beneath the aortic arch could be mistaken for a central pulmonary artery, with disastrous results if shunt procedures without prior cardiac catheterization were undertaken.

Abnormal position of the left brachiocephalic vein beneath the aortic arch is a rare anomaly that can be readily identified by suprasternal cross-sectional echocardiography. Care must be taken not to confuse this venous structure with central pulmonary arteries in the presence of pulmonary atresia, or with a venous confluence in total anomalous pulmonary venous drainage, particularly in the presence of right isomerism and reduced pulmonary flow.

Aortic Dissection in More Than One Family Member

CAROLE A. WARNES, MB, BS, MRCP
PAUL M. KIRKMAN, MD
WILLIAM C. ROBERTS, MD

The occurrence of aortic dissection in 2 or more family members is rare. Such occurred, however, in the father and son described herein.

From the Pathology Branch, National Heart, Lung, and Blood Institute, National Institutes of Health, Bethesda, Maryland, and the Bowman Gray School of Medicine, Wake Forest University, Winston-Salem, North Carolina. Manuscript received and accepted September 5, 1984.

Patient 1: *G.J. (father), a 48-year-old white man who was 66 inches tall (168 cm) and weighed 155 pounds (70 kg), died suddenly on November 15, 1983, without previous evidence of cardiovascular dysfunction. At necropsy examination, a horizontal tear, involving about two-thirds of the aortic circumference, was located 2 cm above the sinotubular junction (Fig. 1), and a medial acute aortic dissection extended from this tear to just proximal to the origin of the innominate artery. The outer media and adventitia in the area of the tear ruptured and 300 ml of blood was present in the pericardial sac. A second dissection (clinically silent), which had healed, involved the descending thoracic and abdominal portions of the aorta. The entrance into the false channel was a tear located just distal to the origin of the left subclavian artery. The heart weighed 440 g and the aortic valve was 3-cuspid and normal. Histologic study of the ascending aorta disclosed it to be normal (Fig. 2).*

Patient 2: *T.J. (son), a 22-year-old student, died on March 25, 1983, after the sudden onset of severe chest pain. He was*

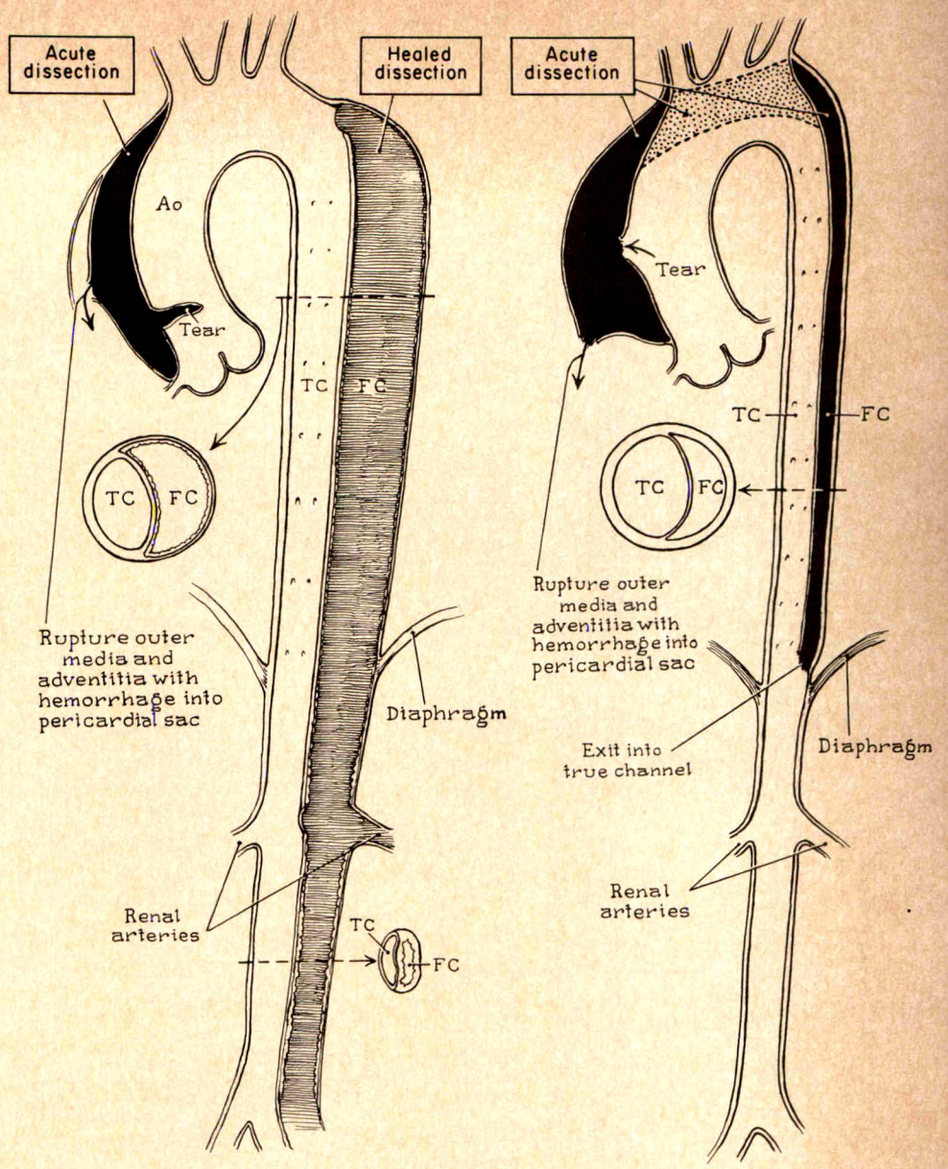

FIGURE 1. Left, drawing illustrating 2 dissections in the father. An acute dissection, which ruptured, began with a tear 2 cm above the sinotubular junction. The healed dissection began in the descending thoracic aorta and involved the entire aorta thereafter. **Right,** drawing illustrating the acute dissection in the son, which began 4 cm above the sinotubular junction and extended to the diaphragm. Ao = aorta; FC = false channel; TC = true channel.

70 inches (178 cm) tall and weighed 175 pounds (80 kg). He had an acute aortic dissection beginning with a tear about 4 cm above the sinotubular junction and extending almost to the level of the celiac axis (Fig. 1). The heart weighed 400 g and the aortic valve was 3-cuspid and normal. Histologic study of the ascending aorta disclosed medial change typical of "cystic necrosis" (Fig. 2).

Neither of these 2 patients or other family members had skeletal or ocular features of the Marfan syndrome (Fig. 3). A search for previous publications describing aortic dissection in more than 1 family member disclosed 12 such reports.[1–12] In the 12 families, 9 of the 26 family members had features highly suggestive of, or diagnostic of, the Marfan syndrome[5,6,8–10]; the 3 patients in the same family reported by Bixler and Antley[12] clearly did not have features of the Marfan syndrome; insufficient information was provided in the remaining 14 patients to be certain about the presence or absence of the Marfan syndrome.[1–4,7,11] Of the 26 patients, at least 24 had died and necropsy was performed in 23.[1–12] The age at death in the 9 parents (6 mothers, 3 fathers)[2,3,5,7–12] and the 1 parents' sister[7] ranged from 31 to 67 years (mean 49), and the ages in the 14 deceased children ranged from 13 to 45 years (mean 29).[2,3,5,7–12] Of the 26 family members, 11 (42%) were women[3,6–10,12] (the age range of the 9 who died was 30 to 62 years [mean 44]) and 15 were deceased males (aged 13 to 67 years [mean 33]).[1–9,11] Of the 24 patients in whom the information was available, the tear was located in the ascending aorta in 18 (69%)[1,2,5–12] and in 13 of them it appears that the entire aorta was involved by the dissection[2,3,5–12]; in the other 6 patients, the tear was in the descending thoracic aorta.[3,4,9,12] More than 1 aortic dissection appeared to have occurred in 3 of the 26 pa-

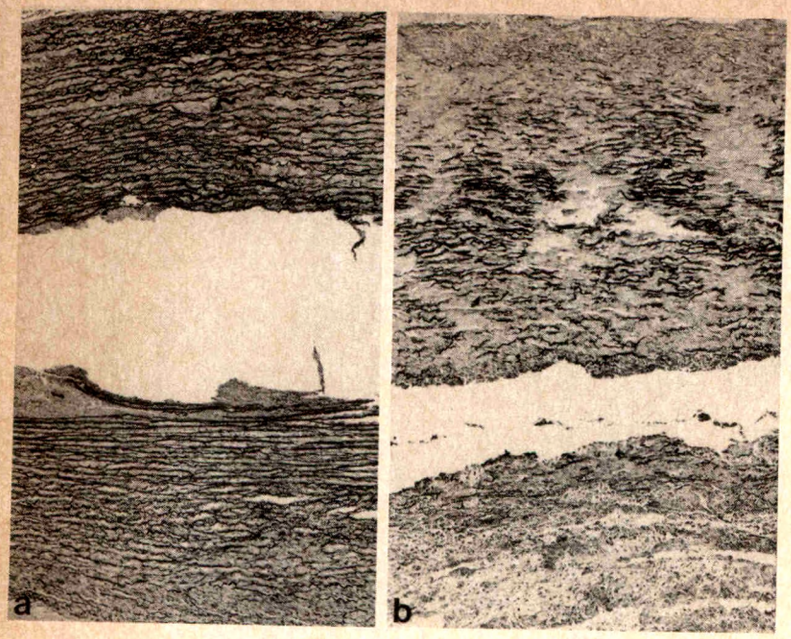

FIGURE 2. Transverse sections of ascending aorta of the father (**a**) and the son (**b**). The configuration of medial elastic fibrils (black) in the father are normal and they are interrupted by fibrous tissue in the son. The space represents the site of dissection. Elastic van Gieson stain; original magnification ×54, reduced 25%.

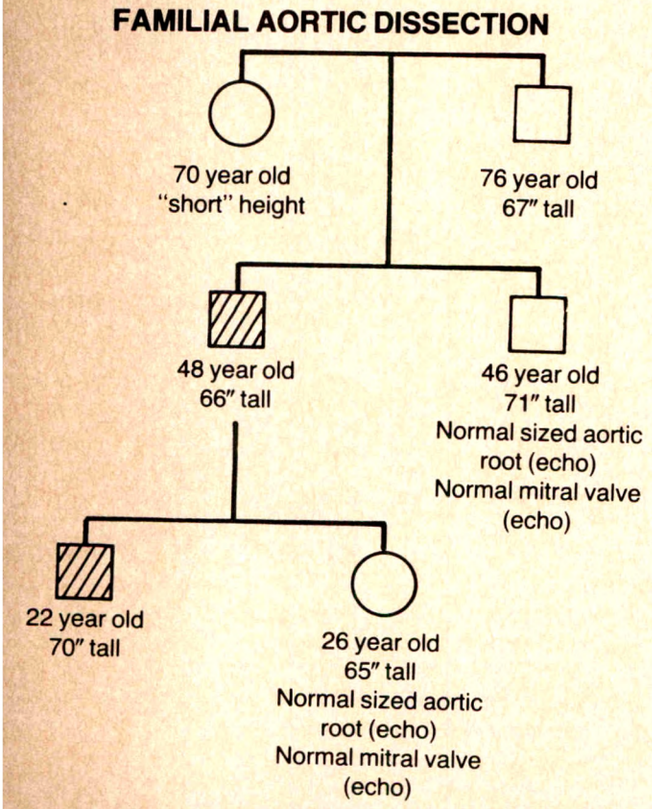

FIGURE 3. Family pedigree. **Squares** and **open circles** are males and females, respectively. **Cross-hatching** denotes the father and son described herein.

tients.[6,8,9] Histologic examination of aorta (portion not always specified) was performed in 20 patients; "cystic medial necrosis" was stated to be present in all 20 (100%). In 1 of our 2 patients, the aortic media was normal histologically. Our 2 patients are particularly unusual in that no family member had features of the Marfan syndrome.

Drug Treatment of Heart Failure

edited by Jay N. Cohn, MD

0-914316-41-9, approx. 250pp., Oct. '83, $35.00

This volume is aimed at providing clinicians with the physiologic and pharmacologic background necessary to effectively and efficiently create and administer drug therapy regimens for their patients who suffer heart failure. All efforts were made to ensure that the timeliness of each chapter, prepared by internationally respected clinicians and medical scientists, would not be compromised by delays in publication. Consequently, this book presents the very latest thinking on the utilization of drug therapy for heart failure and contains many references as recent as 1982 and 1983. This book is highly recommended to all physicians presently treating patients with heart failure.

TABLE OF CONTENTS AND CONTRIBUTORS

Foreword by Jay N. Cohn, MD

Chapter I
The Treatment of Heart Failure in Perspective: An Overview
by Jay N. Cohn, MD

Chapter II
Pathophysiology of Heart Failure: Deficiency in Cardiac Contraction
by John E. Strobeck, MD, and Edmund H. Sonnenblick, MD

Chapter III
The Role of the Renin—Angiotensin—Aldosterone System in the Pathophysiology of Chronic Heart Failure
by Robert J. Cody, MD, and John H. Laragh, MD

Chapter IV
Pathophysiology of Congestive Heart Failure: The Role of The Kidney
by Norman K. Hollenburg, MD

Chapter V
Congestive Heart Failure: Diagnosis and Principles of Treatment
by Elliot Rapaport, MD

Chapter VI
Conventional Drug Therapy in the Management of Heart Failure
by James E. Doherty, MD

Chapter VII
The Role of Inotropic Agents in the Management of Heart Failure
by Gary S. Francis, MD

Chapter VIII
Vasodilator Therapy of Heart Failure
by Kanu Chatterjee, MB, FRCD

Chapter IX
Captopril in Heart Failure
by William W. Parmley, MD

Chapter X
A Comprehensive Approach to the Treatment of Heart Failure
by Jay N. Cohn, MD

Visken® (pindolol)

5-mg and 10-mg Tablets

Before prescribing or administering, see package circular for full product information. The following is a brief summary.

INDICATIONS AND USAGE
Visken® (pindolol) is indicated in the management of hypertension. It may be used alone or concomitantly with other antihypertensive agents, particularly with a thiazide type diuretic.

CONTRAINDICATIONS
Visken (pindolol) is contraindicated in: 1) bronchial asthma; 2) overt cardiac failure; 3) cardiogenic shock; 4) second and third degree heart block; 5) severe bradycardia; (see Warnings).

WARNINGS
Cardiac Failure: Sympathetic stimulation may be a vital component supporting circulatory function in patients with congestive heart failure, and its inhibition by beta-blockade may precipitate more severe failure. Although beta-blockers should be avoided in overt congestive heart failure, if necessary, Visken (pindolol) can be used with caution in patients with a history of failure who are well-compensated, usually with digitalis and diuretics. Beta-adrenergic blocking agents do not abolish the inotropic action of digitalis on heart muscle.

In Patients Without A History of Cardiac Failure: In patients with latent cardiac insufficiency, continued depression of the myocardium with beta-blocking agents over a period of time can in some cases lead to cardiac failure. At the first sign or symptom of impending cardiac failure, patients should be fully digitalized and/or be given a diuretic, and the response observed closely. If cardiac failure continues, despite adequate digitalization and diuretic, Visken (pindolol) therapy should be withdrawn (gradually if possible).

Exacerbation of Ischemic Heart Disease Following Abrupt Withdrawal: Hypersensitivity to catecholamines has been observed in patients withdrawn from beta-blocker therapy; exacerbation of angina and, in some cases, myocardial infarction have occurred after *abrupt* discontinuation of such therapy. When discontinuing chronically administered Visken (pindolol), particularly in patients with ischemic heart disease, the dosage should be gradually reduced over a period of one to two weeks and the patient should be carefully monitored. If angina markedly worsens or acute coronary insufficiency develops, Visken (pindolol) administration should be reinstituted promptly, at least temporarily, and other measures appropriate for the management of unstable angina should be taken. Patients should be warned against interruption or discontinuation of therapy without the physician's advice. Because coronary artery disease is common and may be unrecognized, it may be prudent not to discontinue Visken (pindolol) therapy abruptly even in patients treated only for hypertension.

Nonallergic Bronchospasm (e.g., chronic bronchitis, emphysema)—Patients with Bronchospastic Diseases Should in General Not Receive Beta-Blockers: Visken (pindolol) should be administered with caution since it may block bronchodilation produced by endogenous or exogenous catecholamine stimulation of beta$_2$ receptors.

Major Surgery: Because beta blockade impairs the ability of the heart to respond to reflex stimuli and may increase the risks of general anesthesia and surgical procedures, resulting in protracted hypotension or low cardiac output, it has generally been suggested that such therapy should be withdrawn several days prior to surgery. Recognition of the increased sensitivity to catecholamines of patients recently withdrawn from beta-blocker therapy, however, has made this recommendation controversial. If possible, beta-blockers should be withdrawn well before surgery takes place. In the event of emergency surgery, the anesthesiologist should be informed that the patient is on beta-blocker therapy. The effects of Visken® (pindolol) can be reversed by administration of beta-receptor agonists such as isoproterenol, dopamine, dobutamine, or levarterenol. Difficulty in restarting and maintaining the heart beat has also been reported with beta-adrenergic receptor blocking agents.

Diabetes and Hypoglycemia: Beta-adrenergic blockade may prevent the appearance of premonitory signs and symptoms (e.g., tachycardia and blood pressure changes) of acute hypoglycemia. This is especially important with labile diabetics. Beta-blockade also reduces the release of insulin in response to hyperglycemia; therefore, it may be necessary to adjust the dose of antidiabetic drugs.

Thyrotoxicosis: Beta-adrenergic blockade may mask certain clinical signs (e.g., tachycardia) of hyperthyroidism. Patients suspected of developing thyrotoxicosis should be managed carefully to avoid abrupt withdrawal of beta-blockade which might precipitate a thyroid crisis.

PRECAUTIONS
Impaired Renal or Hepatic Function: Beta-blocking agents should be used with caution in patients with impaired hepatic or renal function. Poor renal function has only minor effects on Visken (pindolol) clearance, but poor hepatic function may cause blood levels of Visken (pindolol) to increase substantially.

Information for Patients: Patients, especially those with evidence of coronary artery insufficiency, should be warned against interruption or discontinuation of Visken (pindolol) therapy without the physician's advice. Although cardiac failure rarely occurs in properly selected patients, patients being treated with beta-adrenergic blocking agents should be advised to consult the physician at the first sign or symptom of impending failure.

Drug Interactions: Catecholamine-depleting drugs (e.g., reserpine) may have an additive effect when given with beta-blocking agents. Patients receiving Visken (pindolol) plus a catecholamine depleting agent should, therefore, be closely observed for evidence of hypotension and/or marked bradycardia which may produce vertigo, syncope, or postural hypotension.

Visken (pindolol) has been used with a variety of antihypertensive agents, including hydrochlorothiazide, hydralazine, and guanethidine without unexpected adverse interactions.

Carcinogenesis, Mutagenesis, Impairment of Fertility: In chronic oral toxicologic studies (one to two years) in mice, rats, and dogs, Visken (pindolol) did not produce any significant toxic effects. In two-year oral carcinogenicity studies in rats and mice in doses as high as 59 mg/kg/day and 124 mg/kg/day (50 and 100 times the maximum recommended human dose), respectively, Visken (pindolol) did not produce any neoplastic, preneoplastic, or nonneoplastic pathologic lesions. In fertility and general reproductive performance studies in rats, Visken (pindolol) caused no adverse effects at a dose of 10 mg/kg.

In the male fertility and general reproductive performance test in rats, definite toxicity characterized by mortality and decreased weight gain was observed in the group given 100 mg/ kg/day. At 30 mg/kg/day, decreased mating was associated with testicular atrophy and/or decreased spermatogenesis. This response is not clearly drug related, however, as there was no dose response relationship within this experiment and no similar effect on testes of rats administered Visken (pindolol) as a dietary admixture for 104 weeks. There appeared to be an increase in prenatal mortality in males given 100 mg/kg but development of offspring was not impaired.

In females administered Visken (pindolol) prior to mating through day 21 of lactation, mating behavior was decreased at 100 mg/kg and 30 mg/kg. At these dosages there also was increased mortality of offspring. Prenatal mortality was increased at 10 mg/kg but there was not a clear dose response relationship in this experiment. There was an increased resorption rate at 100 mg/kg observed in females necropsied on the 15th day of gestation.

Pregnancy—Category B: Studies in rats and rabbits exceeding 100 times the maximum recommended human doses, revealed no embryotoxicity or teratogenicity. Since there are no adequate and well-controlled studies in pregnant women, and since animal reproduction studies are not always predictive of human response, Visken (pindolol), as with any drug, should be employed during pregnancy only if the potential benefit justifies the potential risk to the fetus.

Nursing Mothers: Since Visken (pindolol) is secreted in human milk, nursing should not be undertaken by mothers receiving the drug.

Pediatric Use: Safety and effectiveness in children have not been established.

CLINICAL LABORATORY
Minor persistent elevations in serum transaminases (SGOT, SGPT) have been noted in 7% of patients during Visken (pindolol) administration, but progressive elevations were not observed and liver injury has not been reported in the medical literature over a ten (10) year period of marketing. Alkaline phosphatase, lactic acid dehydrogenase (LDH) and uric acid are also elevated on rare occasions. The significance of these findings is unknown.

ADVERSE REACTIONS
Most adverse reactions have been mild. The incidences listed in the following table are derived from 12 week comparative double-blind, parallel design trials in hypertensive patients given Visken (pindolol) as monotherapy, given various active control drugs as monotherapy, or given placebo. Data for Visken (pindolol) and the positive controls were pooled from several trials because no striking differences were seen in the individual studies, with one exception. The frequency of edema was noticeably higher in positive control trials (16% Visken (pindolol) vs 9% positive control) than in placebo controlled trials (6% Visken (pindolol) vs 3% placebo). The table includes adverse reactions reported in greater than 2% of Visken (pindolol) patients and other selected important reactions.

	Total (Volunteered and Elicited)		
Body System/ Adverse Reaction	**Visken (pindolol) (N = 322) %**	**Active controls* (N = 188) %**	**Placebo (N = 78) %**

* Active Controls: Patients received either propranolol, α-methyldopa or a diuretic (hydrochlorothiazide or chlorthalidone).

More than 7 million patient-years of experience

The following selected (potentially important) adverse reactions were seen in 2% or fewer patients and their relationship to Visken (pindolol) is uncertain. AUTONOMIC NERVOUS SYSTEM: hyperhidrosis; CARDIOVASCULAR: bradycardia, claudication, cold extremities, heart block, hypotension, syncope, tachycardia; GASTROINTESTINAL: diarrhea, vomiting; RESPIRATORY: wheezing; UROGENITAL: impotence, pollakiuria; MISCELLANEOUS: eye discomfort or burning eyes.

POTENTIAL ADVERSE EFFECTS
In addition, other adverse effects not listed above have been reported with other beta-adrenergic blocking agents and should be considered potential adverse effects of Visken (pindolol).

Central Nervous System: Reversible mental depression progressing to catatonia; an acute reversible syndrome characterized by disorientation for time and place, short-term memory loss, emotional lability, slightly clouded sensorium, and decreased performance on neuropsychometrics.

Cardiovascular: Intensification of AV block. See CONTRAINDICATIONS.

Allergic: Erythematous rash; fever combined with aching and sore throat; laryngospasm; respiratory distress.

Hematologic: Agranulocytosis; thrombocytopenic and non-thrombocytopenic purpura.

Gastrointenstinal: Mesenteric arterial thrombosis; ischemic colitis.

Miscellaneous: Reversible alopecia; Peyronie's disease.

The oculomucocutaneous syndrome associated with the beta-blocker practolol has not been reported with Visken (pindolol) during investigational use and extensive foreign experience amounting to over 4 million patient-years.

OVERDOSAGE
No specific information on emergency treatment of overdosage is available. Therefore, on the basis of the pharmacologic actions of Visken (pindolol), the following general measures should be employed as appropriate in addition to gastric lavage:

Excessive Bradycardia: administer atropine; if there is no response to vagal blockade, administer isoproterenol cautiously.

Cardiac Failure: digitalize the patient and/or administer diuretic. It has been reported that glucagon may be useful in this situation.

Hypotension: administer vasopressors, e.g., epinephrine or levarterenol, with serial monitoring of blood pressure. (There is evidence that epinephrine may be the drug of choice.)

Bronchospasm: administer a beta$_2$ stimulating agent such as isoproterenol and/or a theophylline derivative.

A case of an acute overdosage has been reported with an intake of 500 mg of Visken (pindolol) by a hypertensive patient. Blood pressure increased and heart rate was ≥ 80 beat/min. Recovery was uneventful. In another case 250 mg of Visken (pindolol) was taken with 150 mg diazepam and 50 mg nitrazepam, producing coma and hypotension. The patient recovered in 24 hours.

DOSAGE AND ADMINISTRATION
The dosage of Visken (pindolol) should be individualized. The recommended initial dose of Visken (pindolol) is 5 mg b.i.d. alone or in combination with other antihypertensive agents. An antihypertensive response usually occurs within the first week of treatment. Maximal response, however, may take as long as or occasionally longer than two weeks. If a satisfactory reduction in blood pressure does not occur within 3-4 weeks, the dose may be adjusted in increments of 10 mg per day at these intervals up to a maximum of 60 mg per day.

HOW SUPPLIED
White, round, scored tablets: 5 mg and 10 mg, packages of 100. 5 mg tablets embossed "VISKEN 5" on one side, and "78-111" and scored on other side (NDC 0078-0111-05). 10 mg tablets embossed "VISKEN 10" on one side, and "78-73" and scored on other side (NDC 0078-0073-05).

VISKEN FULFILLMENT
555 W. JACKSON
CHICAGO, IL 60606

Please send me clinical background information on Visken (pindolol). I'm interested in how it acts as a beta blocker and a partial beta agonist at the same time to control blood pressure and maintain cardiac output. How does this dual action benefit my patients over 55 who may have elevated blood pressure, impaired cardiac function and increased total peripheral resistance?

VIS-185-9

Clinical Clues to MIXED ANGINA *No. 1*

Thirty seconds ago he was reading

He wasn't exercising; his myocardial oxygen demand didn't increase. Yet now he's having an angina attack.

That's the unpredictability of MIXED ANGINA—vasoconstriction coexisting with fixed coronary lesion, to produce a critical reduction of myocardial blood flow.

And because vasoconstriction is an unpredictable event, ischemia and pain occur unpredictably:

- at rest, or even during sleep
- at varying levels of exercise
- upon exposure to cold
- under emotional stress
- diurnally, typically in the morning

PROCARDIA® (nifedipine) is a primary therapy for the patient with MIXED ANGINA. It prevents vasoconstriction in both large coronary arteries and coronary arterioles to maintain myocardial blood flow and oxygen supply. At the same time, PROCARDIA dilates peripheral arteries to reduce afterload and myocardial oxygen demand.

As a result, PROCARDIA can significantly reduce your patient's angina attack rate and need for nitroglycerin!

PROCARDIA®
(NIFEDIPINE) *Capsules 10 mg*

Primary Protection in
MIXED ANGINA

Please see PROCARDIA® (nifedipine) brief summary on next page.

Thirty seconds ago he was reading.

PROCARDIA®
(NIFEDIPINE) *Capsules 10 mg*

PRIMARY PROTECTION IN MIXED ANGINA

Usual Effective Dosage: 30 to 60 mg/day

For most patients, titrate over 7 to 14 days, using the patient's blood pressure response, attack frequency, sublingual nitroglycerin intake and activity level as a guide. Titration may be more rapid (e.g., 3 days) if symptoms warrant and the patient is observed closely.

Because PROCARDIA decreases peripheral vascular resistance (occasional patients have had excessive hypotension), careful monitoring of blood pressure during initial administration and upward dosage titration is suggested, especially for patients taking drugs known to lower blood pressure. Occasional patients have developed increased frequency, duration or severity of angina on starting PROCARDIA or at the time of dosage increases.

A Favorable Safety Profile

Most frequently reported side effects, usually mild, are dizziness or lightheadedness, peripheral edema, nausea, weakness, headache and flushing, each occurring in about 10% of patients, transient hypotension in about 5%, palpitation in about 2% and syncope in about 0.5%.

1. Stone PH, Muller JE, Turi ZG, et al: Efficacy of nifedipine therapy in patients with refractory angina pectoris: Significance of the presence of coronary vasospasm. *Am Heart J* 106:644-652, 1983.

Brief Summary
PROCARDIA® (nifedipine) Capsules For Oral Use

INDICATIONS AND USAGE: I. Vasospastic Angina: PROCARDIA (nifedipine) is indicated for the management of vasospastic angina confirmed by any of the following criteria: 1) classical pattern of angina at rest accompanied by ST segment elevation, 2) angina or coronary artery spasm provoked by ergonovine, or 3) angiographically demonstrated coronary artery spasm. In those patients who have had angiography, the presence of significant fixed obstructive disease is not incompatible with the diagnosis of vasospastic angina, provided that the above criteria are satisfied. PROCARDIA may also be used where the clinical presentation suggests a possible vasospastic component but where vasospasm has not been confirmed, e.g., where pain has a variable threshold on exertion or in unstable angina where electrocardiographic findings are compatible with intermittent vasospasm, or when angina is refractory to nitrates and/or adequate doses of beta blockers.

II. Chronic Stable Angina (Classical Effort-Associated Angina): PROCARDIA is indicated for the management of chronic stable angina (effort-associated angina) without evidence of vasospasm in patients who remain symptomatic despite adequate doses of beta blockers and/or organic nitrates or who cannot tolerate those agents.

In chronic stable angina (effort-associated angina) PROCARDIA has been effective in controlled trials of up to eight weeks duration in reducing angina frequency and increasing exercise tolerance, but confirmation of sustained effectiveness and evaluation of long-term safety in these patients are incomplete.

Controlled studies in small numbers of patients suggest concomitant use of PROCARDIA and beta-blocking agents may be beneficial in patients with chronic stable angina, but available information is not sufficient to predict with confidence the effects of concurrent treatment, especially in patients with compromised left ventricular function or cardiac conduction abnormalities. When introducing such concomitant therapy, care must be taken to monitor blood pressure closely since severe hypotension can occur from the combined effects of the drugs. (See WARNINGS.)

CONTRAINDICATIONS: Known hypersensitivity reaction to PROCARDIA.

WARNINGS: Excessive Hypotension: Although in most patients, the hypotensive effect of PROCARDIA is modest and well tolerated, occasional patients have had excessive and poorly tolerated hypotension. These responses have usually occurred during initial titration or at the time of subsequent upward dosage adjustment, and may be more likely in patients on concomitant beta blockers.

Severe hypotension and/or increased fluid volume requirements have been reported in patients receiving PROCARDIA together with a beta blocking agent who underwent coronary artery bypass surgery using high dose fentanyl anesthesia. The interaction with high dose fentanyl appears to be due to the combination of PROCARDIA and a beta blocker, but the possibility that it may occur with PROCARDIA alone, with low doses of fentanyl, in other surgical procedures, or with other narcotic analgesics cannot be ruled out. In PROCARDIA treated patients where surgery using high dose fentanyl anesthesia is contemplated, the physician should be aware of these potential problems and, if the patient's condition permits, sufficient time (at least 36 hours) should be allowed for PROCARDIA to be washed out of the body prior to surgery.

Increased Angina: Occasional patients have developed well-documented increased frequency, duration or severity of angina on starting PROCARDIA or at the time of dosage increases. The mechanism of this response is not established but could result from decreased coronary perfusion associated with decreased diastolic pressure with increased heart rate, or from increased demand resulting from increased heart rate alone.

Beta Blocker Withdrawal: Patients recently withdrawn from beta blockers may develop a withdrawal syndrome with increased angina, probably related to increased sensitivity to catecholamines. Initiation of PROCARDIA treatment will not prevent this occurrence and might be expected to exacerbate it by provoking reflex catecholamine release. There have been occasional reports of increased angina in a setting of beta blocker withdrawal and PROCARDIA initiation. It is important to taper beta blockers if possible, rather than stopping them abruptly before beginning PROCARDIA.

Congestive Heart Failure: Rarely, patients, usually receiving a beta blocker, have developed heart failure after beginning PROCARDIA. Patients with tight aortic stenosis may be at greater risk for such an event.

PRECAUTIONS: General: Hypotension: Because PROCARDIA decreases peripheral vascular resistance, careful monitoring of blood pressure during the initial administration and titration of PROCARDIA is suggested. Close observation is especially recommended for patients already taking medications that are known to lower blood pressure. (See WARNINGS.)

Peripheral edema: Mild to moderate peripheral edema, typically associated with arterial vasodilation and not due to left ventricular dysfunction, occurs in about one in ten patients treated with PROCARDIA (nifedipine). This edema occurs primarily in the lower extremities and usually responds to diuretic therapy. With patients whose angina is complicated by congestive heart failure, care should be taken to differentiate this peripheral edema from the effects of increasing left ventricular dysfunction.

Laboratory tests: Rare, usually transient, but occasionally significant elevations of enzymes such as alkaline phosphatase, CPK, LDH, SGOT and SGPT have been noted. The relationship to PROCARDIA therapy is uncertain in most cases, but probable in some. These laboratory abnormalities have rarely been associated with clinical symptoms, however, cholestasis with or without jaundice has been reported. Rare instances of allergic hepatitis have been reported.

Limited clinical studies have demonstrated a moderate but statistically significant decrease in platelet aggregation and increase in bleeding time in some PROCARDIA patients. No clinical significance for these findings has been demonstrated.

Drug interactions: Beta-adrenergic blocking agents: (See Indications and Warnings.) Experience in over 1400 patients in a non-comparative clinical trial has shown that concomitant administration of PROCARDIA and beta-blocking agents is usually well tolerated, but there have been occasional literature reports suggesting that the combination may increase the likelihood of congestive heart failure, severe hypotension or exacerbation of angina.

Long-acting nitrates: PROCARDIA may be safely co-administered with nitrates, but there have been no controlled studies to evaluate the antianginal effectiveness of this combination.

Digitalis: Administration of PROCARDIA with digoxin increased digoxin levels in nine of twelve normal volunteers. The average increase was 45%. Another investigator found no increase in digoxin levels in thirteen patients with coronary artery disease. In an uncontrolled study of over two hundred patients with congestive heart failure during which digoxin blood levels were not measured, digitalis toxicity was not observed. Since there have been isolated reports of patients with elevated digoxin levels, it is recommended that digoxin levels be monitored when initiating, adjusting, and discontinuing PROCARDIA to avoid possible over- or under-digitalization.

Coumarin anticoagulants: There have been rare reports of increased prothrombin time in patients taking coumarin anticoagulants to whom PROCARDIA was administered. However, the relationship to PROCARDIA therapy is uncertain.

When given to rats prior to mating, nifedipine caused reduced fertility at a dose approximately 30 times the maximum recommended human dose.

Carcinogenesis, mutagenesis, impairment of fertility: Nifedipine was administered orally to rats for two years and was not shown to be carcinogenic. When given to rats prior to mating, nifedipine caused reduced fertility at a dose approximately 30 times the maximum recommended human dose. *In vivo* mutagenicity studies were negative.

Pregnancy: Pregnancy Category C. Please see full prescribing information with reference to teratogenicity in rats, embryotoxicity in rats, mice and rabbits, and placental abnormalities in monkeys.

ADVERSE REACTIONS: The most common adverse events include dizziness or lightheadedness, peripheral edema, nausea, weakness, headache and flushing, each occurring in about 10% of patients, transient hypotension in about 5%, palpitation in about 2% and syncope in about 0.5%. Syncopal episodes did not recur with reduction in the dose of PROCARDIA or concomitant antianginal medication. Additionally, the following have been reported: muscle cramps, nervousness, dyspnea, nasal and chest congestion, diarrhea, constipation, inflammation, joint stiffness, shakiness, sleep disturbances, blurred vision, difficulties in balance, dermatitis, pruritus, urticaria, fever, sweating, chills, sexual difficulties, thrombocytopenia, allergic hepatitis, and gingival hyperplasia. Very rarely, introduction of PROCARDIA therapy was associated with an increase in anginal pain, possibly due to associated hypotension.

In addition, more serious adverse events were observed, not readily distinguishable from the natural history of the disease in these patients. It remains possible, however, that some or many of these events were drug related. Myocardial infarction occurred in about 4% of patients and congestive heart failure or pulmonary edema in about 2%. Ventricular arrhythmias or conduction disturbances each occurred in fewer than 0.5% of patients.

HOW SUPPLIED: Each orange, soft gelatin PROCARDIA CAPSULE contains 10 mg of nifedipine. PROCARDIA CAPSULES are supplied in bottles of 100 (NDC 0069-2600-66), 300 (NDC 0069-2600-72), and unit dose (10x10) (NDC 0069-2600-41). The capsules should be protected from light and moisture and stored at controlled room temperature 59° to 77°F (15° to 25°C) in the manufacturer's original container.

Reversible Right Ventricular Outflow Tract Compression by Immunoblastic Sarcoma

PATRICIA C. COME, MD
STEVEN E. COME, MD
MARILYN F. RILEY, BS
LISA V. CARL, BA
SHOICHIRO NAKAO, MD

Various types of tumors, including lymphomas, carcinomas, sarcomas, thymic cysts, thymomas and fibrolipomas, have been detected by echocardiography within the pericardial space or adjacent to the parietal pericardium.[1–6] Echocardiographic recognition of compression of cardiac chambers by extracardiac tumor has been reported in several patients.[1–4] In the patient reported herein, who had an immunoblastic sarcoma, abnormalities indicative of right ventricular (RV) outflow tract obstruction on physical examination, imaging echocardiography and Doppler echocardiography disappeared in association with complete remission of tumor during chemotherapy.

From the Charles A. Dana Research Institute and the Harvard-Thorndike Laboratory of the Beth Israel Hospital, Department of Medicine, Beth Israel Hospital and Harvard Medical School, Boston, Massachusetts.
Manuscript received August 10, 1984; revised manuscript received September 12, 1984, accepted September 13, 1984.

A 34-year-old man was admitted with a several-month history of dry cough, exertional dyspnea and fatigue, pruritus, sweating and a 10-pound weight loss. His heart rate was regular at 104 beats/min, and blood pressure was 120/75 mm Hg, without pulsus paradoxus. There was no jugular venous distention. On cardiac examination, a palpable impulse was felt along the right sternal border only. Heart tones were audible over the right chest, where a fourth heart sound and a grade 4/6 long and mid-peaking systolic ejection-quality murmur were also maximal in intensity. There was no significant adenopathy. Electrocardiographic findings were unremarkable. Chest x-ray revealed a large superior mediastinal mass that displaced the heart to the right. Echocardiographic study revealed posterior displacement of the heart by an 8-cm-diameter mass. RV compression was evident on long- and short-axis parasternal views (Fig. 1). Doppler flow study detected marked turbulence distal to the narrowing (Fig. 2). Biopsy revealed immunoblastic sarcoma of T cell type.

With combination chemotherapy, the symptoms, mass and murmur disappeared. Repeated echocardiographic study revealed disappearance of both the mass and the RV compression (Fig. 1). Doppler study revealed a normal flow signal in the RV outflow tract (Fig. 2).

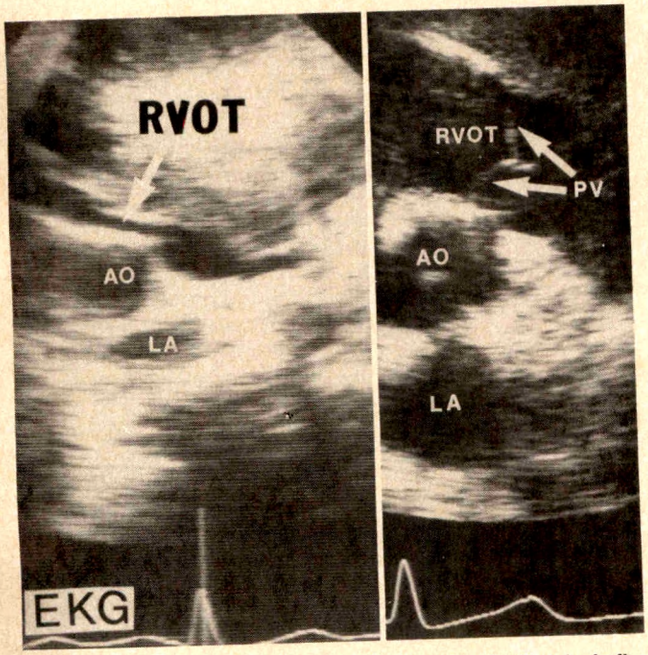

FIGURE 1. Short-axis views at the base of the heart in diastole. **Left,** before chemotherapy, an 8-cm-diameter mass is seen to lie anterior to and to compress the right ventricular outflow tract (RVOT). The pulmonic valve (PV) could not be identified in this plane. **Right,** after chemotherapy, the anterior mass has disappeared and the RVOT has returned to normal size and shape. AO = aortic root; EKG = electrocardiogram; LA = left atrium.

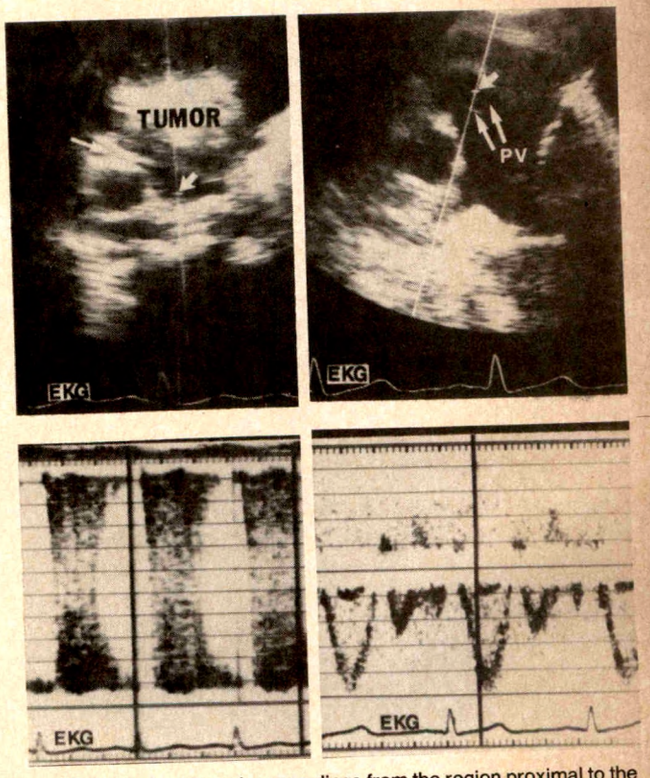

FIGURE 2. Pulsed Doppler recordings from the region proximal to the pulmonary valve leaflets. The **top** tracings, recorded before (**left**) and after (**right**) chemotherapy, illustrate the position of the sample volume (**unlabeled white arrow**). The **bottom** tracings demonstrate the recorded Doppler signals. The 0 reference line is centrally placed in the **right** panel, but has been shifted in the **left** diagram. Each of the **vertical lines** represents 0.5 kHz. The Doppler recording before chemotherapy reveals marked systolic spectral broadening, while that after regression of tumor demonstrates laminar systolic flow. Despite a likely less favorable angle to flow, the kHz shift is greater before chemotherapy than after tumor regression, compatible with tumor-induced obstruction to right ventricular ejection. EKG = electrocardiogram; PV = pulmonic valve.

In our patient, manifestations of subpulmonic stenosis were produced by extrinsic compression of the RV outflow tract by sarcoma. The ejection murmur was long and mid-peaking, compatible with obstruction. On the echocardiogram, the RV outflow tract appeared slit-like in both long- and short-axis views, with its superior border convex toward the lumen. During chemotherapy, RV outflow tract size and shape normalized in association with tumor disappearance. Initial Doppler echocardiography showed marked turbulence proximal to the pulmonary valve. Peak flow velocity could not be determined because cardiac displacement by the tumor made it impossible to orient the Doppler beam in-line with flow. After tumor disappearance, the Doppler beam could be aligned with the presumed direction of flow. The resultant flow signal demonstrated laminar flow, with a lower maximal kHz shift than before chemotherapy, again compatible with disappearance of obstruction.

Imaging echocardiography has greatly facilitated recognition of cardiac involvement by tumor. Doppler echocardiography promises to provide additional information regarding chamber or valvular obstruction or valvular regurgitation in this setting.

Some Unanswered Problems with Probability Analysis: Possible Impact on Exercise Thallium Test Use

RICHARD M. STEINGART, MD
SHUNICHI HOMMA, MD

Probability analysis has been advanced as a means of selecting patient-test combinations that most efficiently lead to a diagnosis in patients with suspected coronary artery disease (CAD).[1] Results of exercise cardiovascular nuclear medicine tests have yielded the greatest shifts in disease likelihood among patients with intermediate pretest likelihoods for disease. Furthermore, the differences in posttest probability produced by nuclear and electrocardiographic exercise tests are greatest among patients with intermediate pretest likelihoods for disease. However, when we examined the actual use of exercise thallium scintigraphy, most patients referred by both house staff and attending physicians had either very high or low pretest likelihoods for disease.[2] One explanation for these ordering practices is a lack of familiarity with probability analysis.[3] Alternatively, the clinical efficacy of a test may not be valued in proportion to its ability to alter disease likelihood. For example, exercise thallium scintigraphy has been advocated as a valuable means of excluding significant coronary disease, particularly when the pretest likelihood for coronary disease is relatively low.[4] In this study we asked house staff to calculate the predictive value of an exercise thallium test result. We then examined the relation between likelihood estimates and stated preferences for testing in an attempt to discover motivations for test ordering in actual practice.

Twenty-six residents in internal medicine, consecutively encountered on the medical service, agreed to fill out a questionnaire in the presence of 1 of the investigators. Subjects were given 4 brief patient histories (Table I) and published values (± standard deviation) for pretest disease likelihood.[5] They also were given the definitions of test sensitivity and specificity in the laboratory at this institution (sensitivity 0.76, specificity 0.88).[2] The subjects were asked to calculate the predictive value of test results for CAD presence, given that patients 1 to 3 had positive test results and patient 4 had a negative test result. The subjects were informed that they should only consider the results as positive or negative because no further information could be gleaned from the test. They were then asked in which patient the thallium exercise test was most useful. Subjects' estimates of predictive values were gathered using a rating scale from 0 to 100%, in divisions of 10%. For each patient, a range of possible posttest likelihoods was calculated by the investigators. This range was determined by using the upper and lower limits of the confidence intervals for pretest disease likelihood in Bayes' theorem (Table II). Any housestaff answer that was within this range was considered correct (Fig. 1).

Study results are presented in Figure 1. Subject performance was best when the thallium test results confirmed an already high (case 3) or low (case 4) pretest likelihood for disease. Greater difficulty was encountered when the test result conflicted with the clinical diagnosis (case 1), or the patient had an intermediate pretest likelihood for disease

From the Division of Cardiology and Department of Nuclear Medicine, Montefiore Medical Center, Albert Einstein College of Medicine, 111 East 210th Street, Bronx, New York 10467.

Manuscript received July 12, 1984; revised manuscript received September 11, 1984, accepted September 13, 1984.

TABLE I Data Provided to House Staff

Pt	Age (yr) & Sex	Hypothetical Patient Problems: Substernal Chest Pain?	Clearly Related to Exertion?	Relieved by TNG?	Disease Prevalence (mean ± SD)[5]	Thallium Test Result
1	35F	+	0	+	4 ± 1	+
2	55M	+	0	+	59 ± 2	+
3	55M	+	+	+	92 ± 1	+
4	45F	+	+	0	13 ± 3	0

TNG = nitroglycerin; + = positive; 0 = negative.

TABLE II Bayes' Theorem

$$\text{Probability of disease given a positive test} = \frac{\text{Sensitivity} \times \text{prevalence}}{(\text{Sensitivity} \times \text{prevalence}) + (1\text{-specificity}) \times (1\text{-prevalence})}$$

$$\text{Probability of disease given a negative test} = \frac{(1\text{-Sensitivity}) \times \text{prevalence}}{((1\text{-Sensitivity} \times \text{prevalence}) + (\text{specificity} \times (1\text{-prevalence}))}$$

(case 2), indicating that the extent to which test results would influence disease likelihood was not precisely understood.

House staff were then asked in which of the 4 patients was the test most useful. Although case 2 was the 1 most frequently selected (12 of 26), most house officers chose a patient at the extremes of pretest disease likelihood (4 each chose cases 1 and 3; 5 chose case 4). One house officer believed the tests to be equally useful. The 4 subjects who selected case 1 (actual posttest likelihood 22%) as most useful overestimated this patient's posttest likelihood at 70%, compared with estimates averaging 21% for those subjects not choosing this testing situation. The 9 subjects who chose cases 3 or 4 as most useful estimated that the test result would slightly increment the diagnostic certainty. The 12 subjects who chose case 2 as most useful estimated the posttest likelihood at 77%, as did those subjects who believed such a test was not particularly useful.

This study demonstrates that house staff estimates of predictive value are accurate only when test results reinforce an already strong clinical impression. The calculations for case 2, the best testing candidate, usually underestimated the power of the test, while those for case 1 often overestimated its power. This overestimation was associated with the preference for testing. However, philosophical differences, rather than differing mathematical abilities, appeared to dictate the preferences of most of the house officers. Despite underestimating the predictive value of the test result in case 2, nearly half valued the marginal value of the positive result in a patient with a truly intermediate chance of having disease. For the remainder, this increment in disease likelihood was not sufficient, and the results in cases 3 and 4 that changed the likelihoods only slightly, but left the least diagnostic uncertainty, were most valued.

Thus, despite extensive attention in the literature, physicians in training are frequently imprecise in the calculation of the predictive value of a test result. At times, these errors appear to contribute to improper test utilization. Many subjects did value the use of the test in the circumstance where, in probabilistic terms, it had the most to offer. However, one-third opted for greater diagnostic certainty, i.e., a more extreme posttest likelihood. These results have implications regarding the threshold approach to clinical decision making. Some studies have examined the use of exercise tests in moving patients above or below somewhat arbitrarily defined threshold probabilities for CAD of 0.90 or 0.10, respectively.[6] Our clinical experience,[2] and the results of the present study, show that physicians often begin testing beyond these thresholds. Because the number of patients with extreme pretest likelihoods is potentially vast, the efficacy of nuclear exercise tests for the diagnosis of CAD should be critically reexamined in this population.

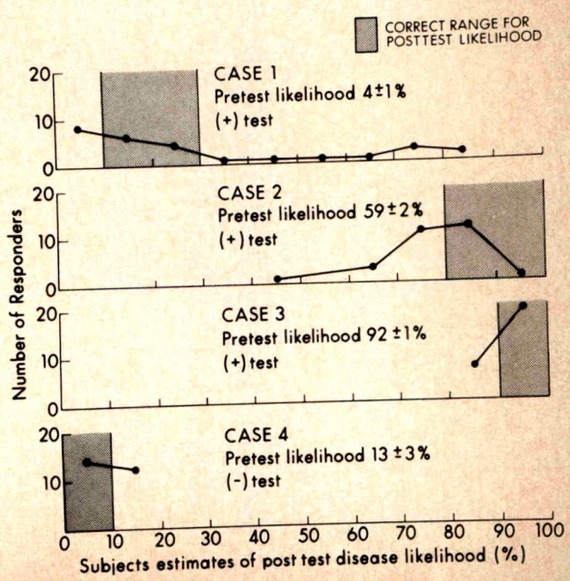

FIGURE 1. House staff estimates of posttest disease likelihood given the published figures for pretest likelihood and test accuracy.

Detection of Atrial Myxoma by Magnetic Resonance Imaging

PETER W. PFLUGFELDER, MD, FRCP(C)
GERALD WISENBERG, MD, FRCP(C)
DEREK R. BOUGHNER, MD, PhD, FRCP(C)

Magnetic resonance (MR) imaging is beginning to show promise for cardiac imaging[1,2] and may offer a high-resolution alternative for the detection and classification of intracardiac masses.

A 45-year-old woman was admitted to the hospital for investigation of chest pain. Examination and electrocardiogram at rest were normal. A submaximal exercise stress test (Bruce protocol), terminated because of fatigue, yielded borderline positive results. A 2-dimensional echocardiogram demonstrated a 2- to 3-cm sessile left atrial (LA) mass adherent to the atrial septum. Cardiac catheterization and coronary arteriography revealed normal coronary arteries. Cardiac fluoroscopy raised the suspicion of calcific deposits in the region of the mass. Forward pulmonary angiography failed to demonstrate an abnormality.

Cardiac MR images were acquired using a Technicare prototype 0.15T (6.25 MHz) resistive MR instrument. Imaging pulse sequences were initiated by an electrocardiographic signal using a modified Honeywell TT-31 telemetry transmitter and receiver. Images were obtained as 2-dimensional single slices using the spin echo (TE 30 and 60 ms) technique in the transverse, sagittal and coronal planes. Imaging was done at end-systole to capture peak atrial filling. Each image required 6 to 8 minutes for acquisition using 4 signal averages per data point. Total study time was 90 minutes. Cardiac and mediastinal anatomy was well defined (Fig. 1). A large, sessile, high-intensity LA mass was clearly seen along the atrial septum. In the TE 60-ms image, normal myocardium is not well visualized, but the mass is highlighted. In this image, a peripheral area of reduced signal is seen in the tumor.

At surgery, a broad-based LA myxoma was found and re-

From the Department of Medicine, Division of Cardiology, St. Joseph's and University Hospitals, University of Western Ontario, London, Ontario, Canada. Manuscript received May 18, 1984; revised manuscript received August 29, 1984, accepted August 31, 1984.

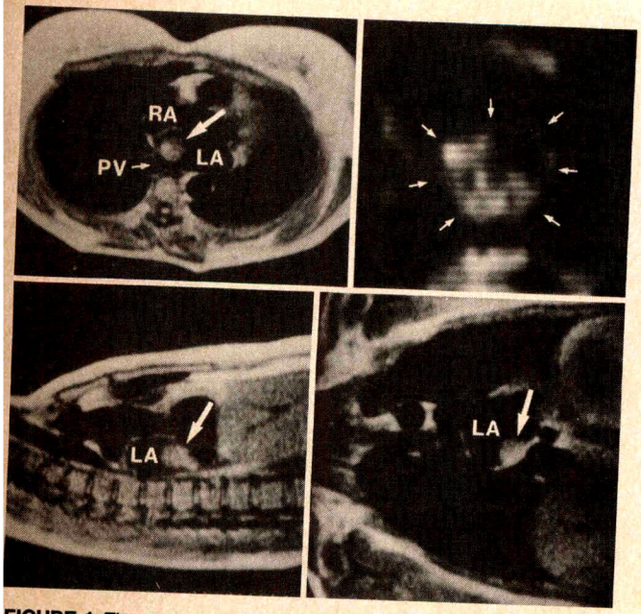

FIGURE 1. The appearance on magnetic resonance imaging of a large left atrial myxoma (**small arrow**) in the transverse (**top left**), sagittal (**bottom left**) and coronal (**bottom right**) planes. These images were obtained using the TE 30-ms sequence. In the TE 60-ms sequence, the tumor is highlighted (**top right**), while normal myocardium is not. LA = left atrium; PV = pulmonary vein; RA = right atrium.

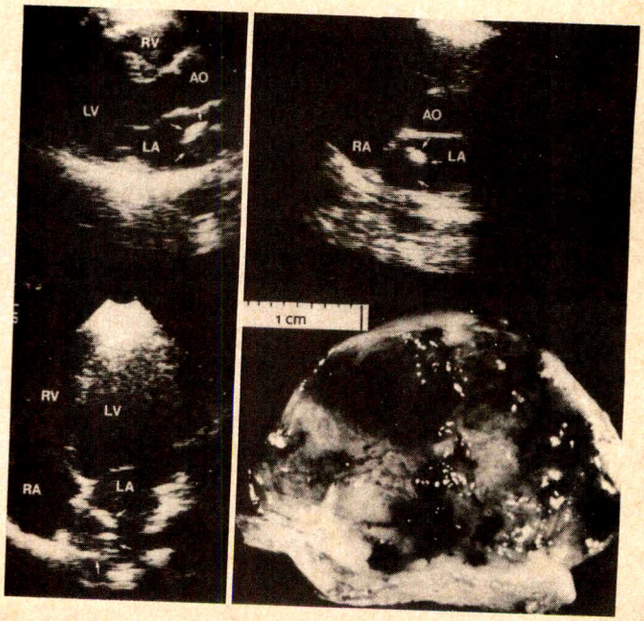

FIGURE 2. Echocardiographic appearance of the myxoma in the parasternal long-axis (**top left**), short-axis (**top right**) and 4-chamber (**bottom left**) views. **Bottom right,** the tumor sectioned in mid-body. AO = aorta; LA = left atrium; LV = left ventricle; RA = right atrium; RV = right ventricle.

sected along with a portion of the atrial septum and LA free wall. Anatomic localization, particularly the relation to the pulmonary vein, was accurately predicted by the MR study. The 3-cm neoplasm contained calcific deposits and areas of hemorrhage (Fig. 2). Microscopic examination revealed the typical appearance of myxoma.

Detection of a LA myxoma by MR imaging has not previously been reported. As the present case illustrates, this technique provides a high-resolution means of detecting intracardiac masses.

MR image signal intensity depends on tissue proton density as well as proton characteristics, termed magnetic relaxation times—T1 and T2. Relaxation times of neoplastic tissue are generally altered, allowing distinction from normal tissue, although specificity for pathologic diagnosis is lacking.[3,4] Characterization and classification of intracardiac masses on the basis of MR relaxation variables has yet to be undertaken. Further experience in this regard will define the potential of MR imaging for providing diagnostic information beyond that of current cardiac imaging techniques.

The AJC in January 1960

WILLIAM C. ROBERTS, MD, and PAUL A. TIBBITS, MD

The January 1960 issue of the AJC contained 19 articles, 11 of which concerned coronary heart disease. The lead article, by Charles Bailey and associates,[1] from Philadelphia, was entitled "Thromboendarterectomy for Coronary Artery Disease." Three years earlier Bailey and associates[2] had reported the first patient to survive coronary endarterectomy and in the present article the results of *coronary endarterectomy* in 15 patients were decribed: 13 patients survived the operation, 1 patient died 8 months postoperatively and 11 were "improved" by the procedure. Of the 15 patients, endarterectomy was performed in 1 coronary artery in 8 patients (left anterior descending in 5) and in 2 or more arteries in 7 patients. A photograph (their Figure 10) showed the endarterectomy specimens in 1 patient to be impressive. The right coronary endarterectomy specimen was 5 cm long and the combined left main and left anterior descending specimen was 9 cm long. The accompanying photomicrograph showed that a portion of media as well as intimal plaque was included in the "endarterectomy" specimen. The procedure was done under complete circulatory bypass. The preoperative angiograms were aortic root injections, not selective coronary arterial injections of contrast material. These extensive coronary endarterectomy procedures combined with aortocoronary bypass are now being performed by Dudley Johnson in Milwaukee, but combined with bypass.

Sigler,[3] from Brooklyn, described 8 necropsy patients with *rupture of the left ventricular free wall during acute myocardial infarction* (AMI). He emphasized the presence of systemic hypertension as the common underlying factor in his patients and in previously reported ones. Now, 25 years later, little additional information has appeared concerning why cardiac rupture occurs in some patients during AMI and not in others. We suspect that the frequency of cardiac rupture during AMI is increasing because arrhythmias, at least during the period of AMI, are far better controlled since the introduction of coronary care units in 1966.

Imperial and associates,[4] from Cleveland, described the frequency of and type of *rate, rhythm and conduction disturbances* as determined by 1 or more random 12-lead electrocardiograms recorded during the first 72 hours of AMI in 153 patients. Some form of disturbance in rate, rhythm or conduction developed in 112 of the 153 patients (73%) and certain forms of disturbances correlated well with the location of the AMI, i.e., whether it involved the anterior or posterior left ventricular wall. Of the 41 patients who had no rhythm or conduction disturbance, 2 (5%) died within 2 years of the AMI; of the 112 patients with a rhythm or conduction disturbance or both, 51 (46%) died within 2 years of the AMI. The frequency of the rate, rhythm and conduction disturbances in the 153 patients was: sinus tachycardia, 28%; sinus bradycardia, 15%; ventricular premature complexes, 12%; atrial fibrillation or flutter, 10%; supraventricular tachycardia, 1%; nodal rhythm, 1%; ventricular tachycardia or fibrillation, less than 1% (1 patient); right bundle branch block, 8%; left bundle branch block, 0, and atrioventricular block, 7% (5 of 10 patients, complete). Continuous electrocardiographic monitoring with the advent of coronary care units, of course, has disclosed the frequency of certain arrhythmias to be much higher than described 25 years ago—ventricular premature complexes by continuous monitoring during AMI has occurred in more than 75% of the patients and ventricular tachycardia in about 25%, for example. Nevertheless, this detailed study by Imperial and associates is important.

Scherf and Bornemann,[5] from New York City, described electrocardiographic results of *blows to the chest after cardiac standstill.* Their 11 case studies and canine experiments clearly demonstrated that mechanical stimulation of the heart offers an immediate, simple, and effective method of cardiac resuscitation during standstill.

An interesting geographic necropsy study by Thomas and associates[6] *compared the frequency of coronary atherosclerosis and myocardial infarcts to the frequency of venous thrombosis and pulmonary embolism* in 3 population groups. The incidence of both acute and healed myocardial infarcts was high in white patients from St. Louis, intermediate in black patients from St. Louis and virtually nil in black patients from Kampala, Uganda, studied at necropsy. The incidence of venous thrombi and pulmonary emboli closely paralleled the incidence of myocardial infarcts in the 3 groups, suggesting that differences in the general tendency of the blood to clot and/or lyse account, at least in part, for the differences in incidences of intravascular thrombosis in the autopsied patients from Uganda and St. Louis.

Stephenson and associates,[7] from Nashville, subjected 330 dogs to 30 minutes of occlusion of their left anterior descending coronary artery. Of 239 dogs

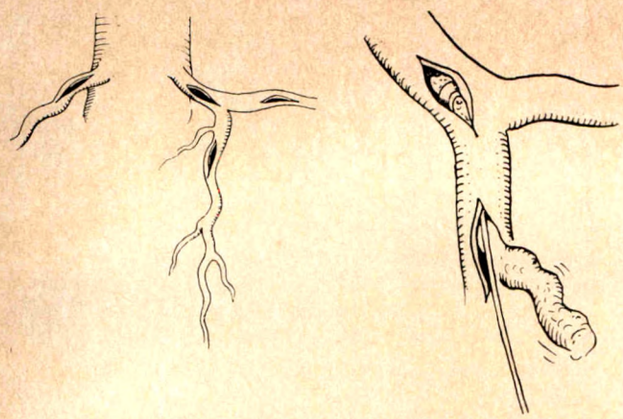

FIGURE 1. Method of performance of coronary endarterectomy. Reproduced with permission of the authors and publisher.[1]

surviving 30 minutes of occlusion, 71% developed ventricular fibrillation (VF) immediately *after* release of the artery, while only 28% of the 330 dogs developed VF *during* the occlusion. The reestablishment of blood flow to an area of myocardium made ischemic thus was more likely to precipitate VF than was the period of ischemia itself. Of course, these dogs previously had normal coronary arteries. Humans with AMI from severe coronary atherosclerosis who have early reestablishment of blood flow to ischemic or necrotic myocardium do not appear to have increased likelihood of development of VF.

Paul Klemperer,[8] who had done much to characterize the various collagen diseases, provided a scholarly historical piece entitled, "The History of Coronary Sclerosis." Why it took so long to connect myocardial infarction to the coronary arteries is nicely explained.

Instructions to Authors (Revised January 1984)

Manuscripts are received with the understanding that they are submitted solely to THE AMERICAN JOURNAL OF CARDIOLOGY, that upon submission, they become the property of the Publisher; that the work has not been previously published, and that the data in the manuscript have been reviewed by all authors, who agree with the analysis of the data and the conclusions reached in the manuscript. The Publisher reserves copyright and renewal on all published material, and such material may not be reproduced without the written permission of the Publisher. Statements in articles are the responsibility of the authors.

ADDRESS MANUSCRIPTS TO: William C. Roberts, MD, Editor-in-Chief, THE AMERICAN JOURNAL OF CARDIOLOGY, 7960 Old Georgetown Road, Suite 2C, Bethesda, Maryland 20814. The covering letter should state precisely and concisely the significance and uniqueness of the work in the authors' view. The authors might delineate the extent of any concessions they are readily prepared to make (for example, the elimination of 1 or more figures or tables or a portion of the text) to increase the likelihood of publication of their work in the *Journal.* Several names and addresses should be provided of nonlocal experts who, in the authors' view, could provide objective and informed reviews of their work. The names of investigators considered unlikely by the authors to give nonbiased reviews of their work may also be submitted.

Submit 3 copies (1 original and 2 xerographic copies) of the entire manuscript, including text, references, figures, legends, and tables. Study recent past issues of the *Journal* for format. Arrange the paper as follows: (1) title page, which should include the title, the full names and academic degrees of the authors, and the institution and city and state or city and country from which the work originated; (2) second title page, with only the title of the article; (3) miniabstract for Table of Contents that includes the full title and names of all authors; (4) abstract; (5) text; (6) references; (7) acknowledgment; (8) figure legends; and (9) tables. Number all pages in the above sequence, beginning with the title page as 1, the abstract as 2, and so on. (Leave the second title page and the miniabstract unnumbered.) Type on 22 × 28 cm (8.5 × 11 inch) paper, only on 1 side of each sheet, double-spaced (including references), with at least 25-mm (1-inch) margins.

The second title page, on which the names and institution of the authors are omitted, gives the Editor-in-Chief the option of acquiring blinded or nonblinded reviews. References to the institution in the text or to the author's previous work in the Reference section must be deleted or written in a manner that prevents identification of the authors and the institution. Label figures with the manuscript title rather than the authors' names so that blinded reviews can be solicited. The authors should state which type of review they wish in the covering letter; this request is always honored.

TITLE PAGE, TABLE OF CONTENTS ABSTRACT AND MINIABSTRACT: For the **complete title page,** include the full first or middle and last names of all authors. Provide a short running title of 3 to 6 words. List the institution and address from which the work originated, and provide information about grant support if necessary. Add at the bottom the phrase, "Address for reprints:" followed by full name and address with zip code.

Limit the **abstract** to 250 words and the Table of Contents **miniabstract** to 150 words. List 2 to 6 **key words** for subject indexing at the end of the abstract.

STYLE: Use appropriate **subheadings** throughout the body of the text, such as the Methods, Results and Discussion. **Abbreviations** are permitted, but no more than 4 per manuscript, and then they must be used on every page of the manuscript after they are initially spelled out (followed by the abbreviation) in both abstract and introduction. Use generic names of drugs. Do not spell out any number, including those less than 10, except when used for opening a sentence, but try not to begin sentences with numbers. Use symbols for less than (<), greater than (>) and percent (%). Indent for paragraphs except the first one in both abstract and introduction. Consult the Uniform Requirements for Manuscripts Submitted to Biomedical journals, published in *The Annals of Internal Medicine* June 1982;96:766–771, and also the *Stylebook/ Editorial Manual of the American Medical Association* for current usage.

REFERENCES: List all authors, year, volume and inclusive pages for all journal references, and specific page numbers for all book references as shown below. Avoid referencing abstracts, but if they are used, indicate them as such by the abbreviation (abstr) after the title. Do not use periods after authors' initials or after abbreviations for titles of journals. Check *Index Medicus* or *Annals of Internal Medicine* (June 1982) as cited above for journal titles and abbreviations. Personal communications, unpublished observations, and manuscripts submitted but not yet accepted for publication do not constitute references.

Journal: Harvey W, Heberden W, Withering W, Stokes W, Murrell W, Einthoven W, Osler W. Anomalies and curiosities of cardiology and of cardiologists. Reflections of famous medical Williams. Am J Cardiol 1984;53:900–915.

Chapter in Book: Cabot RC, White PD, Taussig HB, Levine SA, Wood P, Friedberg CK, Nadas AS, Hurst JW, Braunwald E. How to write cardiologic textbooks. In: Hope JA, ed. A Treatise on Disease of the Heart and Great Vessels. London: Yorke Medical Books, 1984;175–200.

Book: Carrel A, Cutler EC, Gross RE, Blalock A, Craffoord C, Brock RC, Bailey CP, DeBakey ME. The Closing of Holes, Replacing of Valves and Inserting of Pipes, or How Cardiovascular Surgeons Deal with Knives, Knaves and Knots. New York: Yorke University Press, 1984:903.

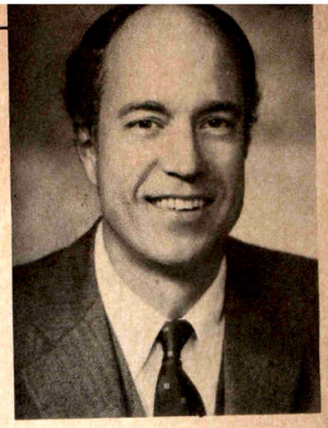
FIGURES: Submit 3 glossy, unmounted prints of each photograph and drawing. Artwork of published articles will not be returned unless requested. Use black ink for all charts (line drawings). Make decimals, broken lines, and so on, clear enough for reproduction. Use arrows to designate special features. Crop photographs to show only essential fields. Identify figures on back by title of the article; omit the authors' names so that blinded reviews can be obtained. Number figures in the order in which they are mentioned in the text. Indicate the top of each figure. Submit written permission from the publisher and author to reproduce previously published figures. Limit figures to the number necessary to present the message clearly. Type **figure legends** on a separate page, double-spaced. Identify at the end of each legend and in alphabetical order all abbreviations in the figure. The cost of color reproduction must be paid by the author.

TABLES: Place each table on a separate page, typed double-spaced. Number each table in Roman numerals (Table I, II, etc.) and title each table. Identify in alphabetical order at the bottom of the table all abbreviations used. When tabulating numbers of patients, use no more than 2 lines, preferably only 1 line, per patient. Use a plus sign (+) to indicate "positive" or "present," a zero (0) for "negative" or "absent," and dash (—) for "no information available" or "not done." Do not use "yes" or "no."

BRIEF REPORTS: Brief Reports must be limited to no more than 3 text pages and 6 references. Longer ones usually will be returned without review. Neither an abstract nor a Table of Contents miniabstract is required for a Brief Report. Subheadings are not used in the body of the Brief Report.

LETTERS (For Publication): The author who submits a letter for consideration for publication should provide a covering letter on his/her own stationery to the Editor-in-Chief stating why the letter should be published. The letter for consideration for publication should be typed, double-spaced, on a separate sheet of plain white paper and limited, with few exceptions, to 2 pages. The original and 2 xerographic copies should be submitted. A title for the letter should be provided at the top of the page. At the end of the letter, the writer's full name and city and state (or country if outside the United States) should be provided. The author's title and institution should not be included. The word "References" does not appear above the list of references in published letters. References should be double-spaced. A letter concerning a particular article in the *Journal* must be received (from authors within the United States) within 2 months of the article's publication.

REPRINTS: Price schedules and order cards for reprints are mailed to the author upon publication of the article. Individual reprints must be obtained through the author.



A Suggestion to Lighten the Load of Manuscript Reviewing

One of the most unselfish acts performed by productive members of the medical academic community is the reviewing of manuscripts submitted for publication by others. The time devoted to this task can be considerable, particularly so for the more prominent members of academia. Many leaders of academia are on the boards of several medical journals simultaneously—not because their names add prestige to the journal, but because they are wise and prompt reviewers whose counsel is widely sought. But reviewing manuscripts takes time away from their own tasks and too much energy expended on others subtracts time devoted to their own creative efforts.

An unfortunate principle of the peer-review process is that the best manuscripts receive the fewest reviews and the worst manuscripts receive the most reviews. The best manuscripts are usually accepted by the first journal to which they are sent. Therefore, they receive 1 to 3 reviews, depending on the policy of the particular journal; the manuscript usually is revised to varying degrees, and then accepted. The process for the less-than-superb or the inferior manuscript is not so rapid. The first journal to which the manuscript is sent may acquire 2 reviews for it, and when neither reviewer recommends acceptance and the editor agrees, the manuscript with the reviews is returned to the submitting author. Then the latter usually submits the manuscript to another journal, ideally after having revised the manuscript as suggested by the reviewers from the first submission. The editor of the journal receiving the previously rejected manuscript then sends it to 2 more reviewers—on occasion, to one who happened to have reviewed the manuscript for the first journal. These reviewers in turn often also provide unfavorable recommendations for the manuscript. The editor then returns the rejected manuscript to the authors, who in turn send it to another journal with or without additional revisions. The duplication process continues.

To prevent this depletion of reviewers' energies and also to prevent further publication delay, I suggest to authors who submit a manuscript rejected by another journal to the AJC that the authors enclose copies of all reviews from the previous journal, a copy of the original manuscript, 3 copies of the revised manuscript, and a response to all items raised by all reviewers from the previous journal. In other words, the response to the reviews from the previous journal should be identical to the response given reviews had they been sent from the AJC. This procedure might allow the AJC editor to make a rapid accept or reject decision on the manuscript, or it might allow him to send the manuscript for reexamination to only 1 reviewer rather than 2. The editor may choose to enclose the reviews from the previous journals' reviewers with the revised manuscript for the new reviewer.

I would welcome a thorough evaluation of this time-saving process and I will do my best not to be offended because the manuscript had not been sent initially to the AJC. I also urge other editors of cardiovascular journals to adopt the same procedure, because all 4 major USA cardiovascular journals essentially use the same pool of reviewers. The concept needs full testing so that the energies for reviewing will be conserved and those energies expended will be utilized more effectively and efficiently.

VENTRICULAR FIBRILLATION DURING CORONARY ARTERIOGRAPHY

Nishimura et al[1] recently reported clinical findings in 39 patients who had ventricular tachycardia or ventricular fibrillation (VF) during coronary arteriography. At St. Lukes Hospital in New York, we undertook a similar study[2] in which we reviewed the records of 66 consecutive patients (1.7% of 3,906 undergoing angiography) who had 69 episodes of contrast-induced VF. In agreement with Nishimura et al,[1] we found few patients with normal coronary arteries (27%), an ejection fraction that was typically normal, a 1.5-times expected frequency of VF after right-sided injections and a wide range of heart rates immediately preceding the arrhythmia.[2] However, we also noted a strong statistical association between temporary right ventricular pacemaker use and the occurrence of VF.[2] We hypothesized that mechanically stimulated ventricular extrasystoles in the setting of a contrast material–induced increase in ventricular vulnerability,[3] at least in some cases, could have accounted for this association. Temporary pacemaker use at our institution is now avoided and the incidence of VF has decreased. It would be of interest to know whether Nishimura et al[1] have data relevant to this issue.

The relation between injection number and occurrence of VF deserves elaboration. As shown in Figure 1, we found that the frequency of VF peaks at the fourth left versus the second right coronary injection. This observation suggests a cumulative effect on the myocardium of Renografin® toxicity; the relatively greater "resistance" to VF during injections of the left coronary artery may relate to a greater degree of dye-dilution in that artery or to the higher left VF threshold.[4]

Finally, the role of Renografin-induced hypocalcemia (via chelation) in prolonging the QT interval deserves mention as an important factor contributing to electrophysiologic instability during coronary arteriography.[3,5,6]

REPLY: The corroborative data presented by Murdock et al and Lehmann provide valuable additional information to our data on ventricular arrhythmias during coronary angiography. They raised the question of an increased incidence of VF during coronary artery bypass graft angiography. They postulate the relation between the relatively large volume of contrast material injected through the graft compared with the mass of perfused myocardium. We would add that grafts supply diseased coronary arteries and often supply blood flow to myocardium with previous ischemic damage. These 2 additional features increase the potential for VF during graft injection. The point of the specific contrast agent used is important. The use of contrast agents without EDTA and sodium citrate may reduce the potential for ventricular arrhythmias. The eventual use of newer, nonionic media may result in a further decrease in the incidence of ventricular arrhythmias.

The information presented by Lehmann is also important. In his study, right ventricular temporary pacing was associated with an increased occurrence of VF. We do not routinely place temporary pacemakers prophylactically, and therefore cannot comment on this factor in our patients. We agree that there may be a cumulative effect of contrast in some patients. In others, there may be both a balance of contrast toxic effects and ischemia. The role of Renografin-induced bradycardia and increased QT-interval prolongation may also be important. It is difficult to analyze the relation of each. We do feel that these postulates and the findings of Lehmann, Murdock, and ourselves, do point out the necessity to allow sufficient time between coronary injections to prevent cumulative toxic effects.

CHARACTERIZATION OF VENTRICULAR FIBRILLATION DURING CORONARY ANGIOGRAPHY

Although ventricular fibrillation (VF) is a well recognized complication of coronary angiography (CA), the clinical and electrocardiographic features of patients who have this complication have received little attention. Thus, the recent investigation by Nishimura et al[1] of 39 patients who have ventricular tachycardia or VF during CA is a welcomed analysis of this complication. We recently completed a similar study involving 8,081 patients in which 63 patients had 68 episodes of VF during CA. Our findings extend on the observations made by these investigators.

We also found that the total number of VF episodes was highest after right coronary artery (RCA) injection (33 of 68), followed by left coronary artery (LCA) injection (21 of 68) and coronary bypass graft injection (14 of 68). However, because only 636 of 8,081 patients undergoing CA had previous aortocoronary bypass surgery, the incidence of VF during bypass graft angiography was 2.2%, which was over 5 times that of an RCA injection (0.41%) and almost 10 times that of an LCA injection (0.25%) ($p < 0.001$). Five of the 39 episodes reported by Nishimura et al[1] followed a bypass graft injection. Although they did not indicate the incidence of VF in the various arteries, considering the relatively small portion of patients in which CA includes bypass graft angiography in most centers, we would suspect that they also had an inordinately high incidence of VF during bypass graft angiography. This observation may be important because the number of patients undergoing CA after bypass surgery will increase in the future. The high incidence of VF after bypass graft injection may result from the relatively large volume of contrast material injected per mass of perfused myocardium. We would also offer this as a possible explanation for VF occurring more often after RCA than after LCA injection.

We also frequently observed some degree of bradycardia before the onset of VF. However, marked bradycardia (≥50% increase in cycle length) preceded VF in only 9% of episodes. Because a similar incidence of bradycardia was also observed in 63 randomly selected patients who did not have fibrillation, bradycardia was not a useful predictor of VF in our study. However, patients in whom bradycardia did precede VF provide some insight into the possible mechanisms involved by suggesting that enhanced automaticity is an unlikely mechanism for the initiation of VF.

Comparing the 63 patients who had VF with 63 randomly selected patients not having VF during CA, we also found no difference with respect to history of arrhythmias, prior myocardial infarction, use of antiarrhythmic agents, age, baseline QT intervals, extent of coronary artery disease or ejection fraction. Thus, we could not identify any clinical feature that would predict the occurrence of VF.

Finally, VF is a direct result of the electrophysiologic effects produced by contrast media.[2–6] All patients in our study and in the study reported by Nishimura et al[1] underwent CA in which Renografin-76® was used as the contrast medium. Considerable experimental animal data indicate that the EDTA and sodium citrate in Renografin-76 may be contributing to this complication.[4–6] If the same holds true for the clinical situation, the incidence of VF during CA may be significantly reduced by using contrast media lacking these additives.

CHEST THUMP ACCELERATION OF VENTRICULAR TACHYCARDIA

I read the report of Krijne[1] on rate acceleration of ventricular tachycardia (VT) after a precordial chest thump. We[2] previously reported 3 patients who had acceleration of VT after a chest thump. All 3 patients were receiving oral digoxin with drug levels above normal at the time of the acceleration of VT. When digoxin was withheld, chest thump successfully terminated further episodes of VT in 2 patients and did not affect the VT in the remaining third patient; however, the phenomenon of VT acceleration was not observed.

CORONARY ARTERY SURGERY STUDY

The editorial titled "The Coronary Artery Surgery Study (CASS): Do the Results Apply to Your Patient?" by Roberts and Manning[1] perpetuates a misconception about the validity of the CASS results despite nonadherence to protocol by more than 25% of the medically assigned patients. This misunderstanding has arisen as a result of a quotation from the CASS report that was taken out of context: "Analyses of CASS mortality data by treatment received and by means of censoring at the time of crossover do not change the results."[2] The next sentence, however, was omitted: "These analyses are not reported since they are of dubious scientific merit in the context of a randomized trial."[2] (emphasis added). The authors of the CASS further stated that, "Given the observed degree of noncompliance to treatment assignment, CASS cannot definitively test the true contrast in outcome between medical and surgical therapy . . . ."[2] If patients deviate from an experimental protocol, they seriously jeopardize the validity of a study. The data may not be simply "reshuffled" and reinterpreted without destroying the randomized nature of the study.

The "intention to treat" principle is a well-established and useful statistical convention, but it should not be used to give legitimacy to studies that may be fatally flawed by nonadherence to the experimental protocol. The policy of analyzing all randomized subjects in the groups to which they were originally assigned ("intention to treat") reduces the risk that a therapeutic benefit will be claimed when none exists. However, the effect of the therapy may be diluted by noncompliant subjects, so that the sensitivity or ability to detect a real difference due to treatment, will be reduced.[3]

Peto et al[4] pointed out that the ability of a clinical study to distinguish between the merits of 2 treatments depends on how many patients die, rather than on the number of patients entered into the study. Suppose, for example, that coronary bypass surgery could prevent as many as 33% of the deaths that would occur in the nonsurgical group. To have only an even chance of demonstrating this fact, we would need to observe 100 deaths; to be safe, the trial should involve, perhaps, 200 deaths. Because the CASS reported only 65 deaths (29 surgical and 36 medical), the observed improvement in survival in the surgical group failed to reach statistical significance. Given the number of deaths in the CASS, there was a low probability that the benefit of coronary artery bypass could be demonstrated.

Gerald S. Weinstein, MD
New York, New York

REPLY: The letter by Weinstein is misleading. In the first paragraph, Weinstein indicates that nonadherence to protocol occurred in over 35% of patients. This is incorrect. The author added together the noncompliance rate in the surgical and in the medically assigned patients to arrive at the

figure of 35%. In actuality, the noncompliance rate is only 17%, i.e., the average of the 11% in the 390 surgical patients and 23.5% in the 390 medical patients. The "intention to treat" approach analyzes the policy or strategy of planned surgical treatment versus the policy or strategy of planned medical treatment. The CASS was never designed as an efficacy study, and any attempt to analyze the data in that way would have been inappropriate.

Weinstein properly points out that in a clinical trial that uses mortality as an endpoint, it is the number of patients who die that ultimately determines the sample size. When there is a clinically meaningful divergence in survival curves between 2 treatment groups, one needs sufficient numbers to prove statistical significance. However, when the 2 survival curves are essentially the same, as was the case in the CASS, then what is the clinical meaning of a minor difference regardless of the numbers used? For example, I do not believe that clinicians would be impressed by a 2% reduction in mortality even if it were statistically significant with 10,000 patients enrolled. Generally, a 20 to 25% reduction in mortality is required to convince physicians of the advantage of a new treatment (e.g., BHAT); the existing CASS data suggests that a 20 to 25% mortality reduction could have not been achieved regardless of the numbers used.

Arthur J. Moss, MD
Rochester, New York
6 September 1984

REPLY: The CASS assessed the long-term benefit of surgical revascularization of the myocardium regarding myocardial infarction (MI) occurrence and survival in patients with mild angina (with or without a prior MI) and in patients who had recovered from a MI without symptoms. After 5.5 years of follow-up there was no significant difference in survival rates or occurrence of MI in those randomized to surgery compared with those randomized to medical treatment. However, there was a greater improvement in symptoms and function in the surgical group. It was concluded from this that surgery can be deferred until symptoms become a problem for the patients despite medical treatment.

Those in the randomized study were a highly selected subgroup of patients with angina or MI; only 5% of those originally screened entered the study. Angiographically normal (or minimal coronary artery disease [CAD]) patients were excluded. Also eliminated were those with severe CAD not suitable for grafting (4.9%). Those with severe angina (36.5%) or left main CAD (found in only 4.3% of 16,000 subjects) were also excluded.

Roberts and Manning conclude from these findings that even coronary angiography should be *avoided* unless symptoms worsen and surgery would be seriously considered on that basis. Weinstein claims that there is a misconception about the CASS findings engendered by a large degree of noncompliance to assigned treatment. However, the study of "randomizable" subjects would appear to reassure on that point, but only if the findings were positive. Weinstein is correct in his assertion that deviation from the experimental protocol does call into question the validity of the study. Subgroup analysis is hazardous if the study was not originally designed to examine these issues. The "intention to treat" principle cannot fully compensate for major nonadherence to the experimental protocol. The bias in the analysis of all randomized subjects keeping them in their originally assigned groups (intention to treat) does minimize the danger of claiming a therapeutic benefit when none exists. But as Weinstein asserts, the effect of therapy can be seriously underestimated by this practice if there is a large amount of crossover or noncompliance.

I agree with Weinstein that the number of events was probably too few to establish a modest difference in survival. In any event, the noncompliance makes a claim of no difference difficult to accept. Only a sizable and significant *difference* would be credible under the circumstances, since this would be a minimal estimate of the effect. The study was not large enough to demonstrate a 50% reduction in the death rate with a better than even chance of this being on the basis of sampling variation. Only a 67% reduction in mortality could be reliably detected (with 0.8 probability). If the actual difference found, whether statistically significant or not, is trivial the issue is moot. There is little virtue in enlarging such a trial to reliably detect differences so small that they would not matter anyway.

We must examine this surgical trial in the context of the epidemiologic perspective on the way coronary artery disease evolves in the general population. This indicates that we must diagnose this disease on its way to happening and correct predisposing factors before the first symptom appears. The first prolonged attack of ischemic chest pain carries a 33% fatality rate and half of all CAD deaths are sudden. One in 6 coronary attacks present with sudden death as the first, last and only symptom. For these, only a preventive approach can be of help.

We do continue to have many CAD patients who have managed to survive MI or have stable angina pectoris. Their outlook, on average, is grim in regard to risk of recurrent MI, cardiac failure, stroke and survival. At this point, when CAD becomes clinically manifest, we are dealing with advanced 2- or 3-vessel CAD and a damaged myocardium. Because we are then dealing with a completed catastrophe, the severity of the CAD at the time of the diagnosis is the chief determinant of the patients' outlook. The standard risk factors at this point have little short-term effect. One risk factor is applicable. Seven studies have shown that quitting cigarette smoking reduces post-MI mortality by 20 to 50%, a result that rivals cardiac surgery or medical treatment. One noteworthy finding of CASS was that 3 of 4 of the 40% of patients who were smoking cigarettes when they entered the trial continued to smoke. Perhaps we should compare medical and surgical treatment with quitting cigarette smoking.

It appears unlikely that surgery alone can restore the damaged myocardium to full function or slow the progression of CAD in patients with angina or a healed MI. The CASS trial suggests that with the advent of better medical treatment, including β-blocking drugs, aspirin and calcium channel-blocking drugs, we can get better results than formerly with respect to both relief of symptoms and survival on medical treatment. What this study may be showing is that bypass surgery is now no better than recently improved medical treatment. Hence we may return to the previously held indications for surgery: angina that the patient cannot tolerate because of life style, personality, inconvenience, or adverse effects from medication. The chief benefit promised is improvement of exercise tolerance and relief of symptoms, but not lengthening of life over medical treatment.

CASS was carried out over a period when CAD mortality in the U.S. was decreasing. The good prognosis of those medically treated was the most noteworthy finding. With modern medical treatment the MI rate was only 2.2% and the mortality rate only 1.6% per year. This may not be entirely due to better treatment, because the decline has not occurred in many European countries with equally sophisticated medical care. Surgical therapy offered no advantage in returning patients to work or in improving their recreational activity. This calls into question surgical indications of rehabilitation and return to work.

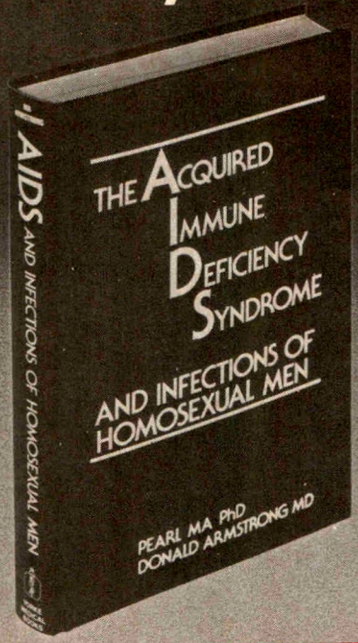
AIDS

An important new book on today's most virulent epidemic



From the Publishers of The American Journal of Medicine, The American Journal of Surgery, and Cutis

Acquired Immune Deficiency Syndrome (AIDS) and Infections of Homosexual Men

edited by **Pearl Ma, PhD,** and **Donald Armstrong, MD** with a foreword by **David J. Sencer, MD,** *Commissioner of Health, New York City; formerly Director, Centers for Disease Control, Public Health Service, U.S. Department of Health and Human Services*

0-914316-38-9, 442 pages, illus., January 1984, $39.50

The first scientific presentation to review all the facts in full

AIDS has become one of the most publicized diseases in modern times. It has produced fear and confusion in the general public and presented a formidable challenge to the medical community. Physicians and scientists have begun work on managing this epidemic, disease control centers continue to search for answers, and the federal government has declared AIDS the number one health priority of the nation. Understanding this disease demands cooperation between many different medical specialties, and papers on this subject have been published in many diverse journals not regularly read by individual specialists. Now, for the first time, two highly distinguished medical experts, Drs. Pearl Ma and Donald Armstrong, have coordinated in one easily accessible volume the complete range of interdisciplinary approaches to this complex disease, with contributions by the most eminent researchers and physicians in disease control and hospital teaching centers throughout the country. Comprehensive coverage is given to the entire spectrum of sexually transmitted diseases, and an additional section on diagnostic perspectives offers never before published material on why this syndrome occurs primarily among homosexual men. For any physician or other health care professional interested in the prevention and cure of this modern epidemic, this book is an indispensable guide to recognizing and treating AIDS and other sexually transmitted diseases.

In Angina,
When Nitrates Alone
Are Not Enough

Add Calan® TABLETS 80 mg and 120 mg (verapamil HCl)

Now Film Coated and Scored

For an improved lifestyle for your angina patients

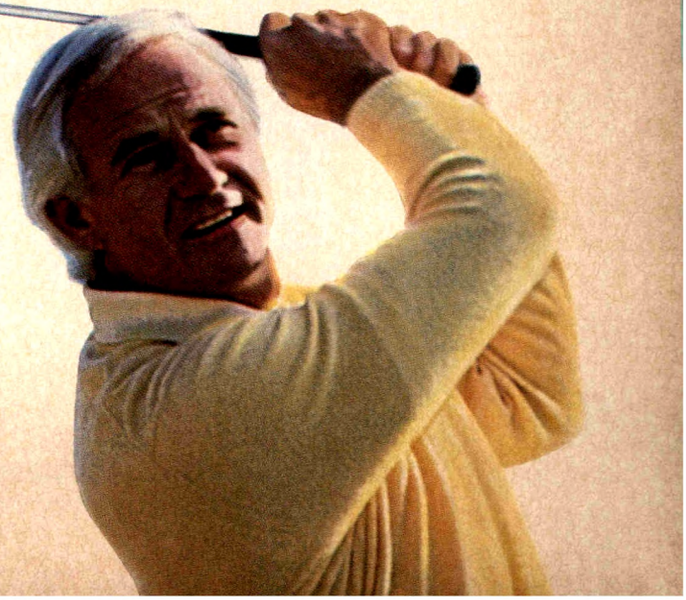
Calan plus nitrates: unique hemodynamic benefits

The addition of Calan improves myocardial perfusion and reduces afterload; the combination also produces a reduction in preload. Not all of these important anti-ischemic effects are seen in therapy with nitrates and beta-blockers. That's why you can expect so many patients to do well on Calan plus nitrates.

Calan plus nitrates: patients feel better, can do more

With this therapeutic combination, patients should be able to exercise longer with fewer attacks — so they will want to do more. The combination also controls any spasm component, and it can be used without special caution in angina patients who also have asthma, COPD, or diabetes.

With Calan, serious side effects are rare. The side effect most commonly seen with Calan is mild constipation. The therapy continuation rate for Calan was 94.5% in clinical studies.



Please see following page for a brief summary of the complete prescribing information.

SEARLE

4W57T

Calan® TABLETS
80 mg and 120 mg
(verapamil HCl)

Contraindications: Severe left ventricular dysfunction (see *Warnings*), hypotension (systolic pressure <90 mm Hg) or cardiogenic shock, sick sinus syndrome (if no pacemaker is present), 2nd- or 3rd-degree AV block.

Warnings: Verapamil should be avoided in patients with severe left ventricular dysfunction (eg, ejection fraction <30%) or moderate to severe symptoms of cardiac failure. Control milder heart failure with optimum digitalization and/or diuretics before Calan is used. Calan may occasionally produce hypotension, usually asymptomatic, orthostatic, mild, and controlled by decrease in Calan dose. Elevations of liver enzymes have been reported. Four cases have been demonstrated to be produced by verapamil. Periodic monitoring of liver function in patients on verapamil is prudent. Patients with atrial flutter/fibrillation and an accessory AV pathway (eg, WPW or LGL syndromes) may develop a very rapid ventricular response after receiving verapamil (or digitalis). Treatment is usually D.C.-cardioversion. AV block may occur (3rd-degree, 0.8%). Development of marked 1st-degree block or progression to 2nd- or 3rd-degree block requires reduction in dosage or, rarely, discontinuation and institution of appropriate therapy. Sinus bradycardia, 2nd-degree AV block, sinus arrest, pulmonary edema and/or severe hypotension were seen in some critically ill patients with hypertrophic cardiomyopathy who were treated with verapamil.

Precautions: Verapamil should be given cautiously to patients with impaired hepatic function (in severe dysfunction use about 30% of the normal dose) or impaired renal function, and patients should be monitored for abnormal prolongation of the PR interval or other signs of overdosage. Studies in a small number of patients suggest that concomitant use of Calan and beta-blockers may be beneficial in patients with chronic stable angina. Combined therapy can also have adverse effects on cardiac function. Therefore, until further studies are completed, verapamil should be used alone if possible. If combined therapy is used, patients should be monitored closely. Combined therapy with verapamil and propranolol should usually be avoided in patients with AV conduction abnormalities and/or depressed left ventricular function or in patients who have also recently received methyldopa. Chronic verapamil treatment increases serum digoxin levels by 50% to 70% during the first week of therapy, which can result in digitalis toxicity. The digoxin dose should be reduced when verapamil is given, and the patient carefully monitored. Verapamil may have an additive hypotensive effect in patients receiving blood-pressure-lowering agents. Disopyramide should not be given within 48 hours before or 24 hours after verapamil administration. Until further data are obtained, combined verapamil and quinidine therapy in patients with hypertrophic cardiomyopathy should probably be avoided, since significant hypotension may result. Adequate animal carcinogenicity studies have not been performed. One study in rats did not suggest a tumorigenic potential, and verapamil was not mutagenic in the Ames test. Pregnancy Category C. There are no adequate and well-controlled studies in pregnant women. This drug should be used during pregnancy, labor, and delivery only if clearly needed. It is not known whether verapamil is excreted in breast milk; therefore, nursing should be discontinued during verapamil use.

Adverse Reactions: Hypotension (2.9%), peripheral edema (1.7%), AV block: 3rd-degree (0.8%), bradycardia: HR <50/min (1.1%), CHF or pulmonary edema (0.9%), dizziness (3.6%), headache (1.8%), fatigue (1.1%), constipation (6.3%), nausea (1.6%); elevations of liver enzymes have been reported (see *Warnings*). The following reactions, reported in less than 0.5% of patients, occurred under circumstances where a causal relationship is not certain: confusion, paresthesia, insomnia, somnolence, equilibrium disorders, blurred vision, syncope, muscle cramps, shakiness, claudication, hair loss, macular eruptions, spotty menstruation, ecchymosis, bruising, gynecomastia, and psychotic symptoms. Overall continuation rate was 94.5% in 1,166 patients.

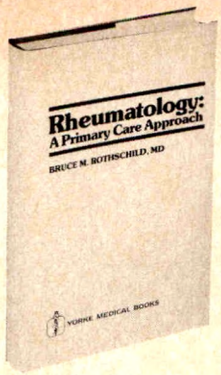
The Diagnosis and Treatment Oriented Approach to Rheumatology with the Primary Care Physician in Mind



Rheumatology

A Primary Care Approach

Written by:

Bruce M. Rothschild, MD

Director, Division of Rheumatology, University Health Sciences, The Chicago Medical School Chief, Section of Rheumatology, V.A. Medical Center North Chicago, Illinois

ISBN 0-914316-33-8, $42.50, 430 pp., illus., 1982.

What is Rheumatology: A Primary Care Approach?

- a succinct (approx. 450 pp.) yet comprehensive presentation of the latest techniques in diagnosis and therapeutic interventions of most use to the primary care physician
- a practical "how-to" desk reference to a difficult but common disease affecting over 35 million patients in the U.S. alone
- a book meant to be used regularly, not read once and stored away on a library shelf
- the primary care physicians' answer to the huge, weighty tomes on Rheumatology which offer too little on diagnosis and treatment and too much on etiology and mechanisms of disease

Abbreviated Table of Contents

Section 1 **Investigative Techniques**
Section 2 **Patterns**
Section 3 **Management**

"This compact, well-designed and generally informative volume is a useful reference for the management of rheumatic disease by physicians who deliver primary care. The family physician will undoubtedly use this frequently as a reference."
Charles M. Plotz, MD American Family Physician

"This book is a good primer for students, residents, and health professionals who would like a glimpse into rheumatology. It can be recommended for all but the specialist (but perhaps the specialist should read it, too, to see what those he is training are learning)."
George E. Ehrlich, MD JAMA September '83

This is a superb text by a sensitive, concerned, organized author of international repute . . . Each chapter is well outlined, concise, practical, and has a current and appropriate bibliography at the end . . . a skillfully structured text which is a quality contribution . . . a very readable text."
John A. Feagin, Jr., MD Military Medicine March '83

SAFER FOR

Digoxin therapy with tablets may be compromised by:

☐ many commonly coadministered drugs, eg, antibiotics, antidiarrheals, antacids, and agents that increase or decrease gut motility

☐ concurrent GI disease: diarrhea, malabsorption syndromes, intestinal diseases, constipation

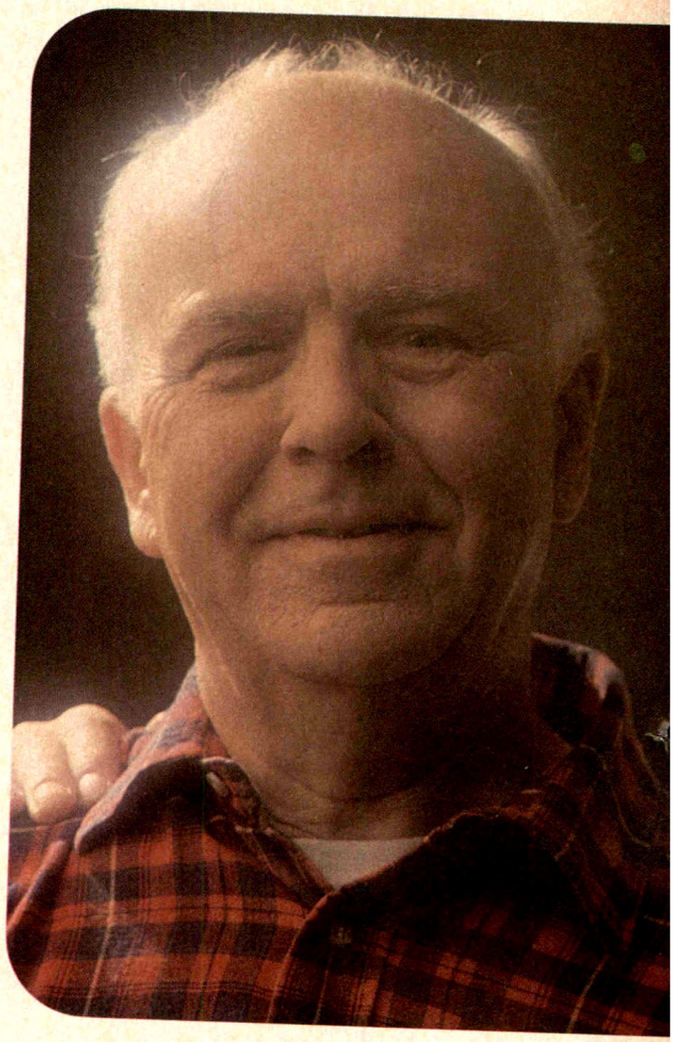
Digoxin therapy with Lanoxicaps® (digoxin solution in capsules) allows the digoxin to be much more rapidly and completely absorbed. Whereas tablet bioavailability is only in the range of 60% to 80%, bioavailability with Lanoxicaps is similar to that following IV administration, 90% to 100%. *Less variability in the amount of digoxin absorbed means less risk of over- or under-digitalization, improving your patient's safety margin.*

"Bioavailability of digoxin has represented one of the most discussed topics of cardiovascular pharmacology of the past decade. The consequent changes in pharmaceutical manufacturing have led to preparations with nearly optimal bioavailability thus favouring a substantial advancement towards a safer treatment."

Levy G, cited by Malini PL, Strocchi E, Negroni S, et al: Greater bioavailability of digoxin in a new capsule preparation. *Current Therapeutic Research* 1983;33:646-650.

"Data collected so far show that if a product is fully bioavailable, the bioavailability in different subjects and in the same subject at different times is within a very narrow range, say 95—100%. However, if a poorly available product has an *average* bioavailability of say 50%, the range in individual patients, and in the same patient at different times, covers a tremendous range, sometimes from 0 to 100%!"

Wagner JG: An overview of the analysis and interpretation of bioavailability studies in man. *Pharmacology* 1972;8:102-117.



The new standard in digoxin

100 μg (0.1 mg) I.D. Imprint B2C (yellow)
200 μg (0.2 mg) I.D. Imprint C2C (green)

Brief Summary of Prescribing Information

Before using Lanoxicaps® (digoxin solution in capsules), the physician should be thoroughly familiar with the basic pharmacology of this drug as well as its drug interactions and its indications and usage.

CONTRAINDICATIONS: Digitalis glycosides are contraindicated in ventricular fibrillation. Any untoward effect requiring permanent discontinuation of other digitalis preparations usually constitutes a contraindication to digoxin. Hypersensitivity to digoxin itself is a contraindication to its use. Allergy to digoxin, though rare, does occur. It may not extend to all such preparations, and another digitalis glycoside may be tried with caution.

WARNINGS: The use of digoxin or other digitalis glycosides in the treatment of obesity is unwarranted and dangerous.

It is recommended that digoxin in soft capsules be administered in divided daily doses to minimize any potential adverse reactions. Where compliance is considered a problem, single daily dosing may be appropriate (see DOSAGE AND ADMINISTRATION section in complete prescribing information).

Anorexia, nausea, vomiting and arrhythmias may accompany heart failure or may be indications of digitalis intoxication. Clinical evaluation of the cause of these symptoms should be attempted before further digitalis administration.

Patients with renal insufficiency require smaller than usual maintenance doses of digoxin (see DOSAGE AND ADMINISTRATION section in complete prescribing information).

Heart failure accompanying acute glomerulonephritis requires extreme care in digitalization. Relatively low loading and maintenance doses and concomitant use of antihypertensive drugs may be necessary. Careful monitoring is essential. Digoxin should be discontinued as soon as possible.

Patients with severe carditis, such as carditis associated with rheumatic fever or viral myocarditis, are especially sensitive to digoxin-induced disturbances of rhythm.

Newborn infants display considerable variability in their tolerance to digoxin. Premature and immature infants are particularly sensitive, and dosage must not only be reduced but must be individualized according to their degree of maturity.

Note: Digitalis glycosides are an important cause of accidental poisoning in children.

PRECAUTIONS:

General: Digoxin toxicity develops more frequently and lasts longer in patients with renal impairment because of the decreased excretion of digoxin. Therefore, dosage requirements will be decreased in patients with moderate to severe renal disease (see DOSAGE AND ADMINISTRATION section in complete prescribing information). More time is required to achieve an initial or new steady-state concentration in patients with renal impairment than in patients with normal renal function.

In patients with hypokalemia, toxicity may occur despite serum digoxin concentrations within the "normal range", because potassium depletion sensitizes the myocardium to digoxin. Hypokalemia may result from diuretic, amphotericin B or corticosteroid therapy, and from dialysis or mechanical suction of gastrointestinal secretions. It may also accompany malnutrition, diarrhea, prolonged vomiting, old age and long-standing heart failure. In general, rapid changes in serum potassium or other electrolytes should be avoided, and intravenous treatment with potassium should be reserved for special circumstances as described below (see TREATMENT OF ARRHYTHMIAS PRODUCED BY OVERDOSAGE section in complete prescribing information).

Calcium, particularly when administered rapidly by the intravenous route, may produce serious arrhythmias in digitalized patients. Hypercalcemia from any cause predisposes the patient to digitalis toxicity. Hypocalcemia can nullify the effects of digoxin in man; digoxin may be ineffective until serum calcium is restored to normal.

Hypomagnesemia may predispose to digitalis toxicity. If low magnesium levels are detected in a patient on digoxin, replacement therapy should be instituted.

Quinidine and verapamil cause a rise in serum digoxin concentration, with the implication that digitalis intoxication may result. This rise appears to be proportional to the dose. Due to the considerable variability of these interactions, digoxin dosage should be carefully individualized.

Certain antibiotics may increase digoxin absorption in patients who convert digoxin to inactive metabolites in the gut (see Pharmacokinetics portion of the CLINICAL PHARMACOLOGY section in complete prescribing information). The magnitude of rise in serum digoxin concentration may be as much as two-fold in some cases. This interaction is significantly reduced if digoxin is given as Lanoxicaps.

Patients with acute myocardial infarction or severe pulmonary disease may be unusually sensitive to digoxin-induced disturbances of rhythm.

Atrial arrhythmias associated with hypermetabolic states (e.g. hyperthyroidism) are particularly resistant to digoxin treatment. Large doses of digoxin are not recommended as the only treatment of these arrhythmias and care must be taken to avoid toxicity. In hypothyroidism, the digoxin requirements are reduced. Digoxin responses in patients with compensated thyroid disease are normal.

Reduction of digoxin dosage may be desirable prior to electrical cardioversion to avoid induction of ventricular arrhythmias, but the physician must consider the consequences of rapid increase in ventricular response to atrial fibrillation if digoxin is withheld 1 to 2 days prior to cardioversion. If there is a suspicion that digitalis toxicity exists, elective cardioversion should be delayed. If it is not prudent to delay cardioversion, the energy level selected should be minimal at first and carefully increased in an attempt to avoid precipitating ventricular arrhythmias.

Incomplete AV block, especially in patients with Stokes-Adams attacks, may progress to advanced or complete heart block if digoxin is given.

In some patients with sinus node disease (i.e. Sick Sinus Syndrome), digoxin may worsen sinus bradycardia or sino-atrial block.

In patients with Wolff-Parkinson-White Syndrome and atrial fibrillation, digoxin can enhance transmission of impulses through the accessory pathway. This effect may result in extremely rapid ventricular rates and even ventricular fibrillation.

Digoxin may worsen the outflow obstruction in patients with idiopathic hypertrophic subaortic stenosis (IHSS). Unless cardiac failure is severe, it is doubtful whether digoxin should be employed.

Patients with chronic constrictive pericarditis may fail to respond to digoxin. In addition, slowing of the heart rate by digoxin in some patients may further decrease cardiac output.

Patients with heart failure from amyloid heart disease or constrictive cardiomyopathies respond poorly to treatment with digoxin.

Digoxin is not indicated for the treatment of sinus tachycardia unless it is associated with heart failure.

Digoxin may produce false positive ST-T changes in the electrocardiogram during exercise testing.

Intramuscular injection of digoxin is extremely painful and offers no advantages unless other routes of administration are contraindicated.

Drug Interactions: Potassium-depleting *corticosteroids* and *diuretics* may be major contributing factors to digitalis toxicity. *Calcium*, particularly if administered rapidly by the intravenous route, may produce serious arrhythmias. *Quinidine* and *verapamil* cause a rise in serum digoxin concentration, with the implication that digitalis intoxication may result. Certain *antibiotics* increase digoxin absorption in patients who inactivate digoxin by bacterial metabolism in the lower intestine, so that digitalis intoxication may result. *Propantheline* and *diphenoxylate*, by decreasing gut motility, may increase digoxin absorption. *Antacids, kaolin-pectin, sulfasalazine, neomycin, cholestyramine* and certain *anticancer drugs* may interfere with intestinal digoxin absorption, resulting in unexpectedly low serum concentrations. *Thyroid* administration to a digitalized, hypothyroid patient may increase the dose requirement of digoxin. Concomitant use of digoxin and *sympathomimetics* increases the risk of cardiac arrhythmias, because both enhance ectopic pacemaker activity. *Succinylcholine* may cause a sudden extrusion of potassium from muscle cells, and may thereby cause arrhythmias in digitalized patients. Although β adrenergic blockers or calcium channel blockers and digoxin may be useful in combination to control atrial fibrillation, their additive effects on AV node conduction can result in complete heart block.

Carcinogenesis, Mutagenesis, Impairment of Fertility: There have been no long-term studies performed in animals to evaluate carcinogenic potential.

Pregnancy: *Teratogenic Effects:* Pregnancy Category C. Digoxin should be given to a pregnant woman only if clearly needed.

Nursing Mothers: Caution should be exercised when digoxin is administered to a nursing woman.

ADVERSE REACTIONS: The frequency and severity of adverse reactions to digoxin depend on the dose and route of administration, as well as on the patient's underlying disease or concomitant therapies (see PRECAUTIONS section). The overall incidence of adverse reactions has been reported as 5 to 20%, with 15 to 20% being considered serious (1 to 4% of patients receiving digoxin). Cardiac toxicity accounts for about one-half, gastrointestinal disturbances for about one-fourth, and CNS and other toxicity for about one-fourth of these adverse reactions.

Adults:

Cardiac—Unifocal or multiform ventricular premature contractions, especially in bigeminal or trigeminal patterns, are the most common arrhythmias associated with digoxin toxicity in adults with heart disease. Ventricular tachycardia may result from digitalis toxicity. Atrioventricular (AV) dissociation, accelerated junctional (nodal) rhythm and atrial tachycardia with block are also common arrhythmias caused by digoxin overdosage. Excessive slowing of the pulse is a clinical sign of digoxin overdosage. AV block (Wenckebach) of increasing degree may proceed to complete heart block.

Note: The electrocardiogram is fundamental in determining the presence and nature of these cardiac disturbances.

Gastrointestinal—Anorexia, nausea, vomiting and less commonly diarrhea are common early symptoms of overdosage. Uncontrolled heart failure may also produce such symptoms.

CNS—Visual disturbances (blurred or yellow vision), headache, weakness, apathy and psychosis can occur.

Other—Gynecomastia is occasionally observed.

Infants and Children: Toxicity differs from the adult in a number of respects. Anorexia, nausea, vomiting, diarrhea and CNS disturbances may be present but are rare as initial symptoms in infants. Cardiac arrhythmias are more reliable signs of toxicity. Digoxin in children may produce any arrhythmia. The most commonly encountered are conduction disturbances or supraventricular tachyarrhythmias, such as atrial tachycardia with or without block, and junctional (nodal) tachycardia. Ventricular arrhythmias are less common. Sinus bradycardia may also be a sign of impending digoxin intoxication, especially in infants, even in the absence of first degree heart block. Any arrhythmia or alteration in cardiac conduction that develops in a child taking digoxin should initially be assumed to be a consequence of digoxin intoxication.

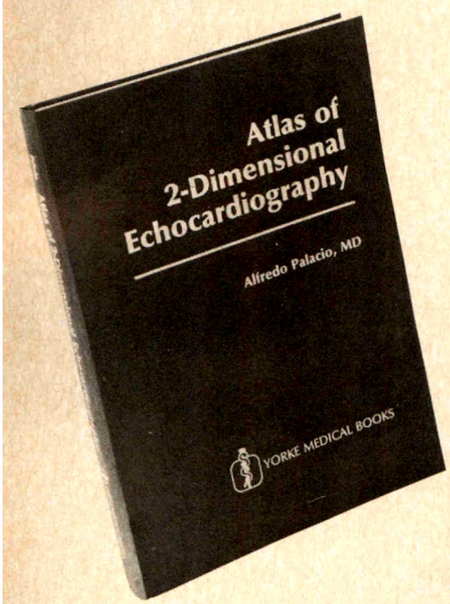
The First Practical Atlas of 2-D Echocardiography Ever Published



A "how-to-do-it" text/atlas presenting the broadest range of normal and abnormal 2-dimensional echocardiograms

Atlas of 2-Dimensional Echocardiography

by Alfredo Palacio, MD
Director of National Institute of Cardiology, Guayaquil, Ecuador
Foreword by David H. Spodick, MD, DSc
Professor of Medicine, University of Massachusetts Medical School;
Director, Division of Cardiology, St. Vincent Hospital, Worcester, Massachusetts

ISBN 0-914316-35-4, 198 pp, illus., large format 8¼ x 12, March '83, $69.00

2-dimensional echocardiography complemented by M-mode echocardiography has become one of the most common noninvasive diagnostic tools used by the cardiologist. With publication of the ATLAS OF 2-DIMENSIONAL ECHOCARDIOGRAPHY, neophyte and expert alike now have available to them the most truly usable didactic presentation of the subject ever published.

A true atlas, this book provides in a **large 8¼ x 12 format 251 black and white half tones, 152 line drawings and 6 charts** which illustrate in exacting detail how to perform and interpret 2-dimensional echocardiograms on patients with existing and/or suspected heart disease. The lucid accompanying text leads the reader step-by-step through the entire process, leaving little to the imagination. It presents in the most simple, direct way possible the broadest range of normal and abnormal 2-dimensional echocardiograms. The descriptions and detailed illustrations in its technical sections will ensure the superior level of performance of echocardiographic techniques that is a sine qua non for good results.

To order your copy of this important new book use the order form to the right.

Table of Contents

Foreword

In choosing a diuretic for the treatment of edema due to congestive heart failure

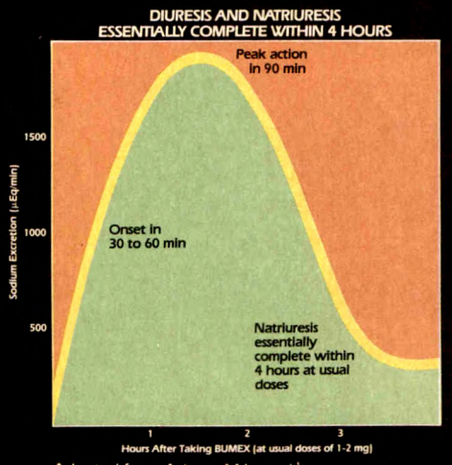
Unsurpassed loop diuretic efficacy

First-pass Radionuclide Angiocardiography displaying a markedly reduced left ventricular ejection fraction in a patient with congestive heart failure. The comparison view (inset at left) shows normal contraction in a patient without heart disease.

Diuresis essentially complete within 4 hours with Bumex at usual doses[1,2]

Faster completion of diuresis with unsurpassed efficacy: that's what makes Bumex easy to live with compared to other loop diuretics.

Bumex rapidly mobilizes a high volume of fluid and sodium in edematous patients with congestive heart failure.[3] And Bumex is unsurpassed in reducing edema and improving the functional status of CHF patients.[4,5]

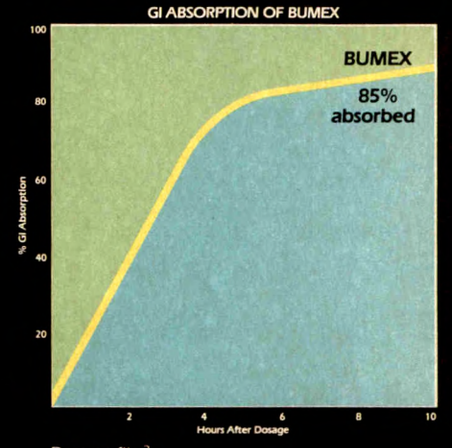


Adapted from Asbury MJ, *et al.*[1]

Effective diuresis through rapid, nearly complete absorption

Eighty-five percent of an oral dose of Bumex is absorbed through the GI tract;[3] thus the diuretic response you can expect with oral Bumex is almost equal in magnitude to the response you get with an I.V. dose.[3,6]

As with all loop diuretics, excessive doses of Bumex can lead to profound diuresis with water and electrolyte depletion, including hypokalemia. Serum electrolytes should be monitored periodically, especially in patients on low-salt diets or those treated for prolonged periods or on high doses.



Data on file.[3]

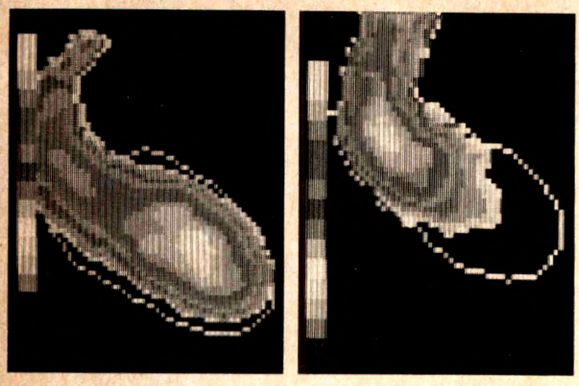
Bumex®

bumetanide/Roche

0.5-mg and 1-mg scored tablets, 2-ml ampuls (0.25 mg/ml)

Faster completion of diuresis that's easier to live with

Faster completion of diuresis... that's easier to live with.



First-pass Radionuclide Angiocardiography displaying a markedly reduced left ventricular ejection fraction in a patient with congestive heart failure. The comparison view (on right) shows normal contraction in a patient without heart disease.

- Essentially completes diuresis within 4 hours, at usual doses
- Among loop diuretics, unsurpassed in volume of fluid and sodium excreted
- Unsurpassed in reducing edema and improving functional status
- Rapidly, nearly completely absorbed—for a predictable diuretic response
- Allows for early-evening diuresis—for days of normal activity, nights of uninterrupted sleep
- Contraindicated in anuria, markedly elevated BUN, hepatic coma and severe electrolyte deficiency
- The most frequent clinical adverse reactions considered probably or possibly related to Bumex are: muscle cramps, dizziness, hypotension, headache, nausea and encephalopathy.

Bumex®
bumetanide/Roche

0.5-mg and 1-mg scored tablets/2-ml ampuls (0.25 mg/ml)

Before prescribing, please consult complete product information, a summary of which follows:

WARNING: Bumex (bumetanide/Roche) is a potent diuretic which, if given in excessive amounts, can lead to a profound diuresis with water and electrolyte depletion. Therefore, careful medical supervision is required, and dose and dosage schedule have to be adjusted to the individual patient's needs. (See under DOSAGE AND ADMINISTRATION in complete product information.)

INDICATIONS AND USAGE: Edema associated with congestive heart failure, hepatic and renal disease, including the nephrotic syndrome.
Almost equal diuretic response occurs after oral and parenteral administration of Bumex. If impaired gastrointestinal absorption is suspected or oral administration is not practical, Bumex should be given by the intramuscular or intravenous route.
Successful treatment with Bumex following instances of allergic reactions to furosemide suggests a lack of cross-sensitivity.
CONTRAINDICATIONS: Anuria. Hypersensitivity and in patients in hepatic coma or in states of severe electrolyte depletion. Although Bumex can be used to induce diuresis in renal insufficiency, any marked increase in blood urea nitrogen or creatinine, or the development of oliguria during therapy of patients with progressive renal disease, is an indication for discontinuation of treatment.
WARNINGS: Dose should be adjusted to patient's needs. Excessive doses or too frequent administration can lead to profound water loss, electrolyte depletion, dehydration, reduction in blood volume and circulatory collapse with the possibility of vascular thrombosis and embolism, particularly in elderly patients.
Prevention of hypokalemia requires particular attention in patients receiving digitalis and diuretics for congestive heart failure, hepatic cirrhosis and ascites, states of aldosterone excess with normal renal function, potassium-losing nephropathy, certain diarrheal states, or other states where hypokalemia is thought to represent particular added risks to the patients.
In patients with hepatic cirrhosis and ascites, sudden alterations of electrolyte balance may precipitate hepatic encephalopathy and coma. Treatment in such patients is best initiated in the hospital with small doses and careful monitoring of the patient's clinical status and electrolyte balance. Supplemental potassium and/or spironolactone may prevent hypokalemia and metabolic alkalosis in these patients.
In cats, dogs and guinea pigs, Bumex has been shown to produce ototoxicity. Since Bumex is about 40 to 60 times as potent as furosemide, it is anticipated that blood levels necessary to produce ototoxicity will rarely be achieved. The potential for ototoxicity increases with intravenous therapy, especially at high doses.
Patients allergic to sulfonamides may show hypersensitivity to Bumex.
PRECAUTIONS: Measure serum potassium periodically and add potassium supplements or potassium-sparing diuretics, if necessary. Periodic determinations of other electrolytes are advised in patients treated with high doses or for prolonged periods, particularly in those on low salt diets.
Hyperuricemia may occur. Reversible elevations of the BUN and creatinine may occur, especially with dehydration and in patients with renal insufficiency.
Bumex (bumetanide/Roche) may increase urinary calcium excretion.
Possibility of effect on glucose metabolism exists. Periodic determinations of blood sugar should be done, particularly in patients with diabetes or suspected latent diabetes.
Patients should be observed regularly for possible occurrence of blood dyscrasias, liver damage or idiosyncratic reactions.
Especially in presence of impaired renal function, use of parenterally administered Bumex should be avoided in patients to whom aminoglycoside antibiotics are also being given, except in life-threatening conditions.
Drugs with nephrotoxic potential and bumetanide should not be administered simultaneously.
Since lithium reduces renal clearance and adds a high risk of lithium toxicity, it should not be given with diuretics.
Probenecid should not be administered concurrently with Bumex (bumetanide/Roche).
Concurrent therapy with indomethacin not recommended.
Bumex may potentiate the effects of antihypertensive drugs, necessitating reduction in dosage.
Interaction studies in humans have shown no effect on digoxin blood levels.
Interaction studies in humans have shown Bumex to have no effect on warfarin metabolism or on plasma prothrombin activity.
Pregnancy: Bumex should be given to a pregnant woman only if the potential benefit justifies the potential risk to the fetus.
Bumetanide may be excreted in breast milk.
Pediatric Use: Safety and effectiveness below age 18 not established.
ADVERSE REACTIONS: Muscle cramps, dizziness, hypotension, headache and nausea, and encephalopathy (in patients with preexisting liver disease).
Less frequent clinical adverse reactions are weakness, impaired hearing, rash, pruritus, hives, electrocardiogram changes, abdominal pain, arthritic pain, musculoskeletal pain and vomiting.
Other clinical adverse reactions are vertigo, chest pain, ear discomfort, fatigue, dehydration, sweating, hyperventilation, dry mouth, upset stomach, renal failure, asterixis, itching, nipple tenderness, diarrhea, premature ejaculation and difficulty maintaining an erection.
Laboratory abnormalities reported are hyperuricemia, azotemia, hyperglycemia, increased serum creatinine, hypochloremia, hypokalemia, hyponatremia, and variations in CO_2 content, bicarbonate, phosphorus and calcium. Although manifestations of the pharmacologic action of Bumex (bumetanide/Roche), these conditions may become more pronounced by intensive therapy.
Diuresis induced by Bumex may also rarely be accompanied by changes in LDH, total serum bilirubin, serum proteins, SGOT, SGPT, alkaline phosphatase, cholesterol, creatinine clearance, deviations in hemoglobin, prothrombin time, hematocrit, platelet counts and differential counts. Increases in urinary glucose and urinary protein have also been seen.
HOW SUPPLIED: *Tablets,* 0.5 mg (light green) and 1 mg (yellow), bottles of 100 and 500; Prescription Paks of 30; Tel-E-Dose® cartons of 100. Imprint on tablets: 0.5 mg—ROCHE BUMEX 0.5; 1 mg—ROCHE BUMEX 1.
Ampuls, 2 ml, 0.25 mg/ml, boxes of ten.

The First Pacemaker With Programming So Simple The Steps Can Be Counted On One Hand.

QUANTUM®

Individually tailoring a cardiac management program has never been so easy.

Follow the five color-coded instructions printed right on the Quantum programmer and you can develop the pacing therapy that's right for your patient. It's as easy as direct-dialing long distance.

Besides being easy to program, Quantum also happens to be today's most advanced VVI pacemaker. Because only Quantum offers you features like transtelephonic real-time, measured telemetry, our exclusive universal Inter-Lock™ connector, a choice of unipolar, bipolar in-line or bipolar bifurcated models and the reliability of redundant circuitry in a case that's just 8 millimeters thin. Which is why Quantum is becoming the choice of physicians seeking optimum control of their patient cardiac pacing programs.

Getting more information on Quantum pacemakers is as easy as programming them. Just call toll-free, 1-800-231-2330 (In Texas call 1-800-392-3726). Or contact your nearest Intermedics representative.

QUANTUM INDICATIONS AND CONTRAINDICATIONS

The indications for cardiac pacing are increasing as pacemakers become more sophisticated and as advanced methods for patient management become more widespread. Generally accepted indications for long-term cardiac pacing include, but are not limited to: (1) sick sinus syndrome; (2) chronic, symptomatic drug-resistant sinus arrhythmias, including sinus bradycardia, sinus arrest, and sinoatrial (S-A) block as seen in sick sinus syndrome; (3) chronic, symptomatic second-degree or third-degree A-V block; (4) recurrent Adams-Stokes syndrome; (5) bradycardia-tachycardia syndrome; (6) symptomatic bilateral bundle branch block; and (7) hypersensitive carotid sinus syndrome (carotid sinus syncope). In addition, certain patients presenting such symptoms as intractable, recurrent congestive heart failure; cerebral or renal insufficiency; or recurrent drug-resistant tachyarrhythmias, and who have been shown to benefit from temporary cardiac pacing, are considered candidates for permanent cardiac pacing.

The indications for permanent pacing in cases of acute myocardial infarction have not yet been rigorously defined. Factors to be considered include the location of the myocardial infarct, the presence or absence of symptoms, ventricular rate, the mechanism of the arrhythmias, and response to therapy. In general, symptomatic drug-resistant bradyarrhythmias that impair cardiac output are considered indications for pacing in patients with acute myocardial infarction, regardless of infarct location.

There are no known contraindications to the use of pacemakers as a medical method for control of heart rate.

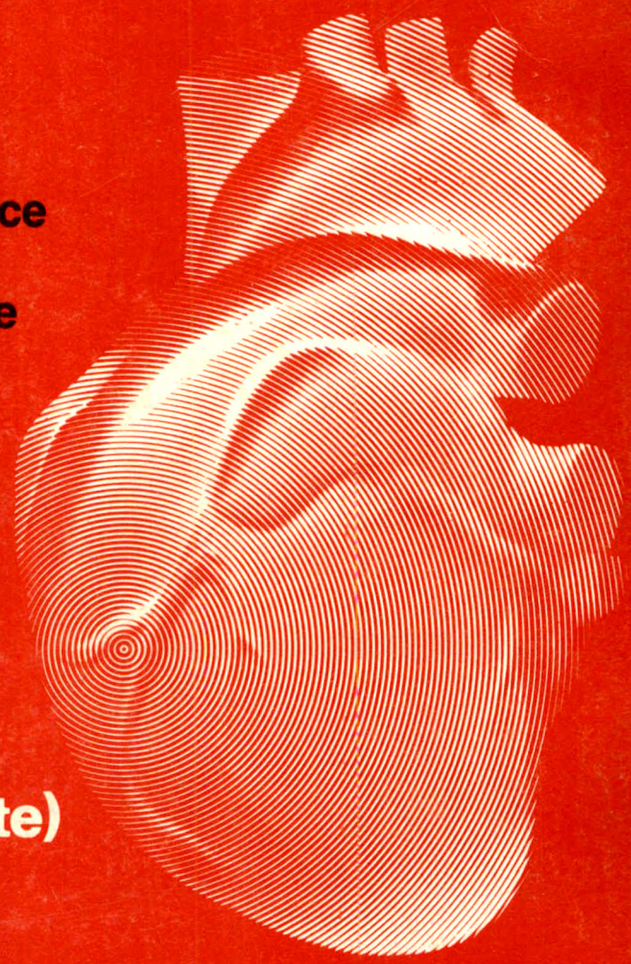
MD10/661 ©Intermedics, Inc., 1984

The Pacekeeper™

For steady maintenance following cardioversion of supraventricular, ventricular, and atrial tachyarrhythmias

- Maintains normal sinus rhythm
- Full quinidine cardiodynamics
- Greater gastrointestinal tolerance than with quinidine sulfate*
- Convenient b.i.d. or t.i.d. dosage

*Bibliography available upon request.



CARDIOQUIN®
TABLETS
(quinidine polygalacturonate)

NDICATIONS AND USAGE: CARDIOQUIN Tablets are indicated as maintenance therapy after pontaneous and electrical conversion of atrial tachycardia, flutter or fibrillation and in the treatment f premature atrial and ventricular contractions, paroxysmal atrial tachycardia, paroxysmal A-V unctional rhythm, atrial flutter, paroxysmal atrial fibrillation, established atrial fibrillation when herapy is appropriate, and paroxysmal ventricular tachycardia when not associated with complete eartblock. CONTRAINDICATIONS: History of hypersensitivity to quinidine, complete A-V block, omplete bundle branch block or other severe intraventricular conduction defects, myasthenia ravis, arrhythmias associated with digitalis toxicity. WARNINGS: In the treatment of atrial ibrillation with rapid ventricular response, use digitalis to control ventricular rate prior to administration of quinidine. In the treatment of atrial flutter, reversion to sinus rhythm may be preceded by rogressive reduction in the degree of A-V block to a 1:1 ratio resulting in an extremely high entricular rate. This potential hazard may be reduced by digitalization prior to administration of uinidine. *Potentially toxic digoxin plasma levels may occur when quinidine is administered oncurrently. Consider reducing digoxin dosage and monitoring for digitalis toxicity.* Evidence f quinidine cardiotoxicity (increased P-R and Q-T intervals, 50% widening of QRS, and/or entricular ectopic beats or tachycardia) mandates immediate discontinuation of the drug, and/or lose clinical and electrocardiographic monitoring. NOTE: Quinidine effect is enhanced by otassium and reduced in the presence of hypokalemia. Quinidine should be used with extreme aution in the presence of incomplete A-V block, since complete block and asystole may result. uinidine may cause abnormalities of rhythm in digitalized patients; therefore, it should be used ith caution in the presence of digitalis intoxication. Caution is also called for in patients exhibiting enal, cardiac or hepatic insufficiency because of potential toxic accumulation of quinidine in lasma. PRECAUTIONS: A preliminary test dose of a single tablet of quinidine sulfate may be dministered to determine if the patient has an idiosyncracy to quinidine. ECG monitoring and etermination of plasma quinidine levels are recommended when doses greater than 2.5 g/day are dministered. Periodic blood counts and liver and kidney function tests should be performed during ng-term therapy.

DRUG INTERACTIONS OF QUINIDINE:

DRUG	EFFECT
With anticholinergic drugs	Additive vagolytic effect.
With cholinergic drugs	Antagonism of cholinergic effects.
With carbonic anhydrase inhibitors, sodium bicarbonate, thiazide diuretics	Alkalinization of urine resulting in decreased excretion of quinidine.
With coumarin anticoagulants	Reduction of clotting factor concentrations.
With tubocurare, succinylcholine and decamethonium	Potentiation of neuromuscular blockade.
With phenothiazines and reserpine	Additive cardiac depressive effects.
With hepatic enzyme-inducing drugs (phenobarbital, phenytoin, rifampin)	Decreased plasma half-life of quinidine.
With digoxin	Increased plasma concentrations of digoxin (see WARNINGS)

PREGNANCY: The use of quinidine in pregnancy should be reserved only for those cases where the benefits outweigh the possible hazards to the patient and fetus. NURSING MOTHERS: The drug should be used with caution due to excretion of the quinidine in breast milk. ADVERSE REACTIONS: SYMPTOMS OF CINCHONISM (ringing in the ears, nausea, headaches, and/or disturbed vision) may appear in sensitive patients after a single dose of the drug. GASTROINTESTINAL: Diarrhea, nausea, vomiting, abdominal pain. CARDIOVASCULAR: Widening of QRS complex, cardiac asystole, ventricular ectopic beats, idioventricular rhythms (including ventricular tachycardia and fibrillation), paradoxical tachycardia, arterial embolism, and hypotension. HEMATOLOGIC: Acute hemolytic anemia, hypoprothrombinemia, thrombocytopenic purpura, agranulocytosis. CNS: Headache, fever, vertigo, apprehension, excitement, confusion, delirium, and syncope, disturbed hearing (tinnitus, decreased auditory acuity), disturbed vision (mydriasis, blurred vision, disturbed color perception, reduced vision field, photophobia, diplopia, night blindness, scotomata), optic neuritis. DERMATOLOGIC: Rash, cutaneous flushing with intense pruritus, urticaria. HYPERSENSITIVITY REACTIONS: Angioedema, acute asthmatic episode, vascular collapse, respiratory arrest, hepatic toxicity. See package insert for Full Prescribing Information.

New Concepts in the Mechanisms and Treatment of Congestive Heart Failure

Introduction

JAY N. COHN, MD

Recent reawakening of interest in the syndrome of congestive heart failure (CHF) can be attributed to several factors:

(1) Sophisticated noninvasive and invasive techniques make quantitation of impaired left ventricular function more available than in the past.

(2) New pharmacologic approaches demonstrate the ability to produce striking augmentation of depressed ventricular function and thus are stimulating physicians to become more aggressive in the management of patients with CHF.

(3) Follow-up of patients with signs or symptoms of CHF reveals a far more grim prognosis for survival than previously suspected.

(4) More than a decade of extensive experience with coronary angiography and coronary artery bypass surgery reveals that left ventricular dysfunction may be the most important factor determining prognosis.

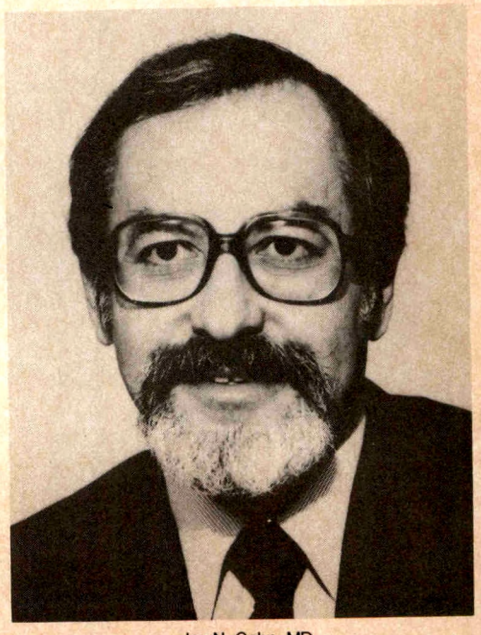
The burgeoning reports on pathophysiologic, clinical and therapeutic aspects of CHF and the wide array of therapeutic options now available for the management of the syndrome have placed a burden on the clinician to make complex management decisions in a rapidly changing environment. How should the severity of CHF be assessed? How can the prognosis be predicted? How aggressive should treatment be? Which drugs should be used and in which order? How can clinical response be monitored? The present symposium does not pretend to answer these substantive clinical questions; instead, it provides a framework within which the clinician may build an understanding of the syndrome and a rational approach to management.

From the Cardiovascular Division, Department of Medicine, University of Minnesota Medical School, Minneapolis, Minnesota.

Address for reprints: Jay N. Cohn, MD, Box 488 Mayo, University of Minnesota, Minneapolis, Minnesota 55455.

McFate Smith opens the symposium with an analysis of data relating to the epidemiology of CHF. Despite generations of experience with this clinical syndrome, the absence of rigorous criteria for diagnosis and classification has hindered the collection of reliable information. Furthermore, the epidemiologic characteristics of the syndrome are probably changing as our population ages, as treatment for hypertension becomes more effective and as our ability to assess ventricular function more accurately becomes more widespread.

The pathophysiology of CHF is reviewed by William Parmley, who describes the role of various etiologic factors, changes in cardiac muscle and pump function,



Jay N. Cohn, MD

biochemical abnormalities, peripheral vascular alterations and therapeutic implications of this disturbed physiology. Gary Francis provides a scholarly review of the neurohumoral mechanisms that may contribute to inappropriate peripheral vasoconstriction in CHF. Rapid expansion of our understanding of the cellular mechanisms controlling activity of the sympathetic nervous system and of our insight into the abnormalities of neural control in CHF may someday contribute to new approaches to long-term management.

Use of quantitative exercise testing with measurement of respiratory gas exchange is a valuable tool in assessing the severity and monitoring the course of patients with CHF. Karl Weber and Joseph Janicki review their extensive experience with this method and provide physiologic background information that is important for understanding the usefulness and interpretation of such testing.

Therapeutic approaches to heart failure are considered by Barry Levine, Robert Cody and Edmund Sonnenblick. Levine addresses the use of vasodilators for reducing preload and impedance as a means of improving left ventricular pump function. Cody describes his studies with enalapril, a new converting-enzyme inhibitor that appears to produce a sustained improvement in cardiac function and exercise performance. Sonnenblick and associates review the concept behind the development of new inotropic drugs and discuss where such agents may fit in our overall schema for managing CHF.

The sketchy data available on the natural history and therapeutic efficacy of various interventions in CHF make it clear that additional well-controlled studies are urgently needed to place management of this common and lethal disorder on a more rational basis. The problems in designing such studies are reviewed in the paper by Curt Furberg and associates at the National Heart, Lung, and Blood Institute. Plans are under way to undertake a multicenter national study under NHLBI auspices to evaluate preventive and therapeutic aspects of CHF. Furberg's contribution describes the rationale for the planned approach. The multicenter Veterans Administration Cooperative Study (V-HEFT), scheduled for completion in 1985, may provide new insights into natural history and therapeutic responses that may help to answer some questions and is also likely to raise others.

CHF is a pathophysiologic entity of great heterogeneity. Prevention of progression of the syndrome rather than treatment of its end stage appears to be the more likely approach to be successful in altering its prognosis. But how to recognize the early stage of the syndrome and how to intervene are problems still to be resolved.

Epidemiology of Congestive Heart Failure

WILLIAM McFATE SMITH, MD

Despite the paucity of epidemiologic work on congestive heart failure (CHF), the salient features of the natural course of cardiac failure are understood. The estimated 1983 incidence of CHF in the United States was 214,000 men and 184,000 women. The estimate of prevalence was 2.3 million persons, with a remarkable increase with advancing age and higher rates in men than women at all ages. Overt heart disease plus age are the principal determinants of the incidence of CHF. Nearly 90% of patients with CHF have systemic hypertension or coronary heart disease, or both, as the antecedent underlying condition. Diabetes mellitus increases the risk of CHF at all ages, particularly in women and those treated with insulin. The prognosis after diagnosis of CHF is grim and is related to the degree of myocardial dysfunction. The challenge is to develop more effective drugs not only for the management of overt CHF, but also for the prevention of its progression. (Am J Cardiol 1985;55:3A–8A)

During the past 3 decades, the epidemiologic method has been increasingly applied to the search for the causes of the major chronic degenerative diseases. Systemic hypertension and atherosclerosis are perhaps the most notable examples. Congestive heart failure (CHF), of course, is not a disease, but "a pathophysiologic state in which an abnormality of cardiac function is responsible for failure of the heart to pump blood at a rate commensurate with the requirements of the metabolizing tissues."[1] Nonetheless, because the epidemiologic approach involves the assessment of the distribution pattern of *any* event of medical concern in populations, in accordance with some characteristic that is believed to influence the occurence of the event (e.g., age, sex, race, body type and antecedent medical history), it is appropriate to apply the epidemiologic method to understanding the causes and prognostic implications of cardiac failure.

Little epidemiologic study relating to CHF has been done, and virtually all studies before Framingham were hampered by the absence of uniform diagnostic criteria and differing observational methods applied under differing circumstances to different populations. The available mortality data, autopsy studies and morbidity data based on hospital statistics did not readily translate into community prevalence rates. Nonetheless, certain salient features of the natural course of cardiac failure were understood and projections of the magnitude of the problem in terms of prevalence and incidence were not grossly inaccurate. We are also certain that CHF is a common consequence of a variety of underlying causes. Moreover, despite modern management, CHF has a dismal prognosis, with only 50% of patients surviving 5 years after diagnosis.

Prevalence

Before the Framingham study, the best estimates of prevalence based on mortality rates varied from 0.05 to 2/1,000 per year. Clinical wisdom held that CHF was more frequent in the elderly patient and was the usual cause of death in heart disease. Morbidity estimates drawn from private practice and hospital wards led Paul Dudley White to conclude that CHF developed in more than half of all persons with organic heart disease. Klainer et al[2] reported that 1 to 2% of total admissions to selected hospitals in Australia, Canada and the United States were for cardiac failure. Community prevalence rates cannot be drawn from such data; however, in communities in which the population at risk is well defined, such rates give some indication of the prevalence of CHF serious enough to warrant hospitalization. Using the 1960 U.S. census data and such hospital statistics, it was suggested that 1% of the population had cardiac failure and that the admission rate for CHF was approximately 2/1,000 population per year (Table I). The hospital data also supported the clinical impression of a strong correlation of CHF with advancing age, with up to 80% of patients admitted in 2 series older than 60 years of age.

Survey studies of physicians in two U.S. counties Montgomery, North Carolina, and Caledonia, Vermont) were conducted in 1962 by Gibson et al[3] and provided prevalence rates for all ages and both sexes of to 10/1,000 population. Age-specific rates demonstrated a remarkable increase in CHF with increasing ge. The incidence of new cases during the survey period projects to 3.8/1,000 per year in one county and 5.0/1,000 population per year in the other.

Based upon these data, Gibson et al estimated that in 1960 1.4 million persons in the US had CHF and that 1.7 million would have it in 1970 and to 1.9 million in 1980. Similarly, the estimated incidence of new cases was projected to rise from 220,000 to 250,000 to 300,000 (Table II). The projection for 1980 based on the physician survey in the 2 rural counties in the early 1960s is not substantially different from that based on the Framingham rates and the 1981 U.S. census.

Incidence

Aside from the aforementioned physician survey information, incidence data on the occurrence of CHF in the general population were almost nonexistent before the Framingham study. Using uniform criteria for diagnosis based on a schema that had worked well for a rheumatic fever study, data were compiled for 20 years of follow-up of 5,192 men and women who had no evidence of cardiac failure on entry.[4,5] Of these, 117 men and 102 women aged 45 to 74 years developed definite CHF. Age-specific rates doubled for both men and women at each decade, averaging 3.7/1,000 for men and 2.5/1,000 for women (Table III). The rate of cardiac failure in men exceeded that for women at all ages, presumably because of the greater prevalence of coronary heart disease in men.

Prognosis

The natural history of cardiac failure in the absence of treatment intended to improve myocardiac contractility or reduce edema or afterload is not available. Neither are controlled trial data to assess the impact of these treatment modalities on long-term mortality, although the clinical impression that short-term mortaility improves is probably accurate. The Framingham study found that the probability of death within 4 years of first diagnosis of cardiac failure was 52% for men and 34% for women, regardless of the underlying cause. (Table IV).[6] Within 5 years of a first myocardial infarction, 14% of men had CHF, and half were dead within 5 years.[4,5]

From a population of 1,964 medically treated patients found to have significant coronary artery disease during cardiac catheterization at Duke University Medical Center over a 12-year period, the prognosis of 236 patients with a history of cardiac failure was examined.[7]

The ejection fraction had been determined in 196 (83%) of these patients.

Of 133 deaths, 54 (41%) occurred within 2 hours of the onset of symptoms and were classified as sudden. Forty deaths (30%) were the result of progressive cardiac failure. Other fatal cardiac events were due to recurrent myocardial infarctions (n = 28) and stroke (n = 6). There were 18 nonfatal infarctions and 6 noncardiovascular deaths. The cumulative initial event rates were 37% and 67% at 1 and 5 years, respectively (Fig. 1). The survival probabilities were not different for New York Heart Association classes I to III, 75% and 48% at 1 and 5 years, but were notably worse for class IV, 34% and 18% at 1 and 3 years, respectively (Fig. 2).

The prognosis of 77 patients with functional class III or IV heart failure was evaluated prospectively at the University of Pennsylvania over 5 to 40 months (average 12).[8] Survival was computed by life-table analysis and related to clinical hemodynamic M-mode echocardiography and 24-hour Holter monitoring data. Overall survival was 52% at 1 year and 32% at 2 years. The cause of cardiac mortality was equally divided between sudden death and cardiac failure. The survival rate for patients with underlying coronary artery disease was no different from other causes.

Survival experience was described[9] in men with severe cardiac failure caused by coronary artery disease or idiopathic dilated cardiomyopathy. This population consisted of patients with persistent symptoms despite therapy, who were referred for management and long-term follow-up by cardiologists at the Veterans Administration Hospitals in Philadelphia and Minneapolis. A total of 182 patients, 95 with cardiomyopathy secondary to coronary artery disease and 87 with idiopathic dilated cardiomyopathy, were followed for an average of 12 months. During the follow-up period, 88 deaths occurred, 58 in the coronary artery disease group and 30 in the idiopathic group, a difference significantly greater than expected by chance ($p < 0.01$). Forty-two percent of the deaths in the coronary artery disease group and 50% of those in the idiopathic group were classified as sudden. Among the patients who underwent coronary arteriography, mortality in the coronary artery disease group was 49% at 1 year and 82% at 2 years, compared with 17% and 48% at 1 and 2 years, respectively, for patients with idiopathic dilated cardiomyopathy. Survival rates for the etiologic groups were analyzed separately and together. By 3 years only 24% of the patients were alive, but the cumulative mortality was clearly higher for the coronary artery disease group at 12 and 24 months (Fig. 3).

Thus, CHF is highly lethal even from the time of first diagnosis, and can only be described as grim once symptoms do not yield to treatment.

Risk Factors

Overt heart disease whether ischemic, rheumatic or congenital, plus advancing age, are the principal determinants of the incidence of CHF. There are other, more subtle predictors, some of which are etiologic and some merely markers of deteriorating myocardial function. Among the former, none is more dominant

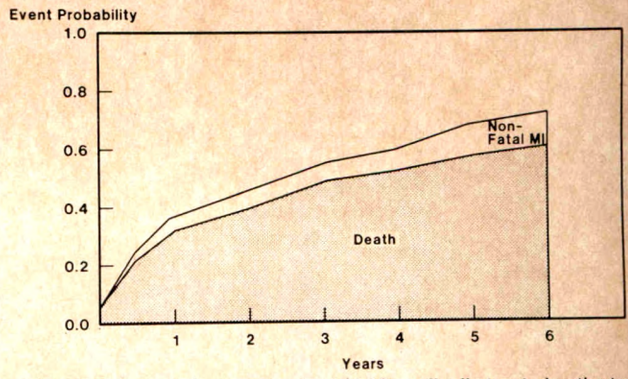

FIGURE 1. Cumulative event rates in 236 medically treated patients with coronary disease and congestive heart failure. MI = myocardial infarction.

than hypertension. And, although this association was noted much earlier, it was the report of 16 years of follow up of the Framingham study that placed this in its present perspective.[4–6]

Systemic hypertension: Definite hypertension preceeded CHF in 75% of cases, and was the rule even in those patients who also had coronary artery disease and rheumatic heart disease. Indeed, coronary artery disease not accompanied by hypertension was a precursor to cardiac failure in only 10% (Fig. 4). Women were as susceptible as men to elevated blood pressure as a precursor to CHF. In regression models of CHF incidence on blood pressure, the contribution of blood pressure was also independent of other cardiovascular risk factors. This prediction of risk applies to diastolic, mean and systolic pressure equally well. Indeed, the coefficients for the regression of CHF incidence on systolic pressure were larger than those for diastolic (0.643 vs 0.466).

Diabetes mellitus: Other frequently noted concomitant chronic diseases, such as diabetes mellitus, chronic lung disease, stroke and claudication, are all probably related to advanced age, but only diabetes

mellitus may be uniquely related to CHF. The Framingham study examined this relation in some detail, noting antecedent diabetes in 16% of patients who had cardiac failure.[10] This apparent excess reflected a greater impact on women than men (Table V). Diabetic women had a 5-fold increase in incidence of CHF while diabetic men only had a 2-fold greater risk compared with nondiabetic persons. This excess risk of CHF conveyed by the diagnosis of diabetes applied to all ages, but was substantially limited to those diabetics treated with insulin, who constituted 40% of those diagnosed (Table VI). More than half of the patients with diabetes who had cardiac failure were taking insulin. This finding may implicate insulin-dependent, ketotic, insulinopenic diabetes of early onset as the promoter of cardiac failure rather than mere duration or severity of the diabetes. A sizable and unique effect of diabetes persisted in multivariate analysis, which also took into account other coronary heart disease risk factors and other possible contributors to CHF incidence. Thus, rather than simple acceleration of coronary atherosclerosis, it has been suggested that it is microangiopathy similar to that seen in the skin, retina and kidney, and known to be more severe in the insulin-dependent diabetics, that increases the risk of CHF.

Other factors: Proteinuria, obesity and cigarette smoking were also examined in the Framingham cohort as possible promoters of CHF.[6] Proteinuria was associated with an excess risk of cardiac failure, even when other cardiovascular risk factors associated with proteinuria were taken into account. A modest effect of weight on age-adjusted risk of CHF for all ages combined was noted. Cigarette smoking was, at best, a weak predictor of cardiac failure in men, but doubled the risk in women.

Prognostic Factors

The studies at Duke University Medical Center found no distinction among New York Heart Association classes I to III patients in terms of a number of baseline characteristics (abnormalities), including a history of myocardial infarction.[7] On the other hand, class IV patients had substantially more abnormalities (Fig. 2). Moreover, multivariate analysis demonstrated that the most important predictors of survival were class IV CHF together with significant left main stenosis, decreased ejection fraction and widened a-v oxygen difference. Unfortunately, the considerable overlap of hemodynamic measurements between survivors and nonsurvivors, especially in classes I to III, limited the

usefulness of these variables as discriminators among individual patients and in evaluation of therapeutic interventions. Moreover, these hemodynamic variables often do not correlate well with the symptomatic status of patients with CHF.

The University of Pennsylvania study found a correlation between survival and global circulatory dysfunction as indicated by functional class during the first 4 months of enrollment, but thereafter found no clinical or hemodynamic variable that correlated with survival.[7] The study also found a positive correlation of ventricular tachycardia (5 or more consecutive ventricular premature depolarizations) with functional class and nonsudden cardiac mortality, but no variable that correlated with sudden death (Fig. 5).

On the other hand, the Veterans Administration study of patients with refractory symptoms (classes III and IV) found that the hemodynamic measures of left ventricular dysfunction correlated well with prognosis. In addition, it noted a worse prognosis in patients with higher systemic vascular resistance, lower left ventricular stroke work and high levels of circulating catecholamines (Figures 6 and 7).[9] The need to activate the adrenergic system and perhaps the renin-angiotensin-aldosterone system appears to herald a particularly grave prognosis. In view of the correlation of hemodynamic variables with prognosis even in advanced cases, the Veterans Administration investigators believed their use may have value if their modification would alter prognosis. The question is: which of the variables to intervene on, or because the options include cardiotonics, diuretics and afterload reducers, in what combination and sequence should one commence?

Implications

Based on the criteria used in the Framingham study and the observed rates, the estimate for the 1983 inci-

dence of CHF in the United States is 214,000 men and 184,000 women.

The estimate of prevalence based on the 2-county study of Gibson and applied to the 1981 census figures is 2,300,000. In 1981, 1.8 million physicians' office visits were for CHF. Over 1.5 million hospital discharges in 1982 bore the diagnosis of CHF, with the rate of hospitalization for CHF ranging up to 20/1,000 population (2%) in the older age category. CHF was the underlying or contributing cause of death in 164,000 persons in 1978. All of these figures are strikingly related to age, with men having higher rates than women at all ages. Nearly 90% of these patients have hypertension or coronary heart disease or both, with hypertension predominating as the antecedent underlying condition.

The prognosis after first diagnosis is grim; less than half survive after 5 years. Prognosis is related to the degree of myocardial dysfunction. For example, functional class IV has a 1-year survival rate of less than 50%, with nearly half of the deaths classified as sudden.

If there exists a wide spectrum of degree of myocardial dysfunction, ranging from that which can only be detected by sophistocated measures (invasive and noninvasive) during stress (class 0), through that which can be recognized clinically under varying degrees of stress (classes I and II), to global insufficiency even at rest (class IV), then the challenge is to develop more effective drugs for both the management of overt cardiac failure and the prevention of its progression.

Ultimately, the goal must be prevention. Given the dominance of hypertension as a risk factor in the development and progression of CHF, drugs that are effective in controlling blood pressure through afterload reduction also have the potential for impacting on the natural history of CHF.

Pathophysiology of Congestive Heart Failure

WILLIAM W. PARMLEY, MD

Over the past several years, additional information has been accumulated on the pathophysiology of congestive heart failure. The primary cardiac defect is a decrease in intrinsic contractility of the myocardium, usually brought on by prolonged pressure or volume overload. Several associated biochemical changes have been described, although no precise cause-and-effect relation has been determined. A number of neurohumoral changes occur, which increase systemic vascular resistance. This increased resistance contributes further to a decrease in cardiac output. In fact, many such "compensatory mechanisms" that are initially beneficial may overshoot and produce deleterious hemodynamic effects. Therapeutic interventions such as diuretics, inotropic drugs and vasodilators are frequently helpful by correcting compensatory mechanisms that overshoot. (Am J Cardiol 1985;55:9A–14A)

Congestive heart failure (CHF) is a common clinical syndrome but its pathophysiologic factors may vary considerably among patients. An overview of the major factors involved in CHF and a discussion of the therapeutic implications of these changes are presented.

Causes of Heart Failure

Table I lists some of the major pathophysiologic processes that contribute to the development of CHF. Pressure overload is commonly caused by systemic hypertension or by outflow tract obstruction, such as valvular aortic stenosis. Similarly, the right ventricle can be affected by pulmonary hypertension of any origin. Volume overload can be caused by several different conditions, such as aortic or mitral regurgitation. High output states, which will be discussed later, can also contribute to volume overload of the left ventricle. Selective volume overload of each ventricle can be caused by certain forms of congenital heart disease. For example, a patient with an atrial septal defect and a large left-to-right shunt will have volume overload of the right ventricle, whereas the left ventricle will be unaffected. Prolonged pressure or volume overload leads to intrinsic changes in myocardial contractility, which appear to be mostly irreversible.[1] This decline in contractility eventually results in the common clinical syndrome of CHF.

Loss of muscle as a cause of CHF is best exemplified by the patient with coronary artery disease who has one or more myocardial infarctions. This loss of muscle decreases the pumping capabilities of the heart and can lead to the same irreversible changes in the remaining normal myocardium. In acute myocardial infarction, for example, loss of 40% or more of the myocardium results in cardiogenic shock.[2]

A decrease in the intrinsic contractility of heart muscle is exemplified by conditions such as volume and pressure overload and cardiomyopathy. The last general factor listed in Table I is restricted filling of the heart. This is exemplified by constrictive pericarditis, pericardial tamponade or conditions in which a stiff ventricular chamber restricts filling. Examples of the latter include endomyocardial fibrosis or a thick hypertrophied ventricle with decreased compliance. In many of these settings, the atrial contribution to ventricular filling becomes an important mechanism for maintaining filling of the left ventricle. For example, when atrial fibrillation develops in patients with hypertrophic cardiomyopathy, the loss of the A-wave contribution frequently leads to abrupt development of the signs and symptoms of CHF.

With these general factors in mind, Table II is a list of the common clinical causes of heart failure seen in patients with this syndrome. In our experience, coronary artery disease is the most common cause of CHF. It comprises approximately two-thirds of our patients with severe class IV heart failure. It appears that systemic hypertension is becoming a less common cause of severe CHF, presumably reflecting better recognition and control of elevated blood pressure. Similarly, rheumatic valvular disease appears to be declining as a common cause of severe CHF. This probably reflects the decreased incidence of the condition and better surgical management at an earlier stage of the disease. Calcific aortic stenosis in older patients, however, remains an

important cause, but it may be difficult to recognize because its manifestations are often relatively subtle. Cardiomyopathy is a not infrequent cause of CHF. Controversy has arisen as to whether these patients should undergo cardiac biopsy to determine the potential for immunosuppressive therapy.[3] Frequently, the cause of cardiomyopathy cannot be determined, although we presume that many idiopathic cardiomyopathies represent postviral events.

The most common cause of right-sided cardiac failure is left-sided cardiac failure. However, a number of important conditions lead to pulmonary hypertension and right-sided cardiac failure in the absence of direct involvement of the left ventricle. Mitral stenosis is one of these conditions, although its incidence appears to be decreasing in the U.S. Emphysema and chronic obstructive lung disease, particularly in association with smoking, are frequent causes of elevated pulmonary pressures and right-sided cardiac failure. Repeated pulmonary emboli may also cause this syndrome. Idiopathic pulmonary hypertension is not uncommon, yet there is inadequate knowledge regarding causative factors. Heart failure associated with congenital heart disease can occur at all ages, depending on the particular syndrome involved. Many cardiovascular abnormalities lead to CHF during the neonatal period and some are virtually incompatible with life. Earlier and more complete correction of many abnormalities has decreased the number of patients who present with CHF in their later years.

Cardiac Function in Heart Failure

By implication, most of the entities discussed so far lead to a reduction in cardiac output, which is one of the principal manifestations of the CHF state. However, high-output failure can be produced by a number of conditions. Furthermore, in some patients with reduced ventricular reserve any increased need for cardiac output can precipitate CHF. Table III lists some of the common causes of increased cardiac output that may contribute to CHF in either a primary or secondary fashion. Hyperthyroidism increases the need for cardiac output by increasing total body metabolism, as mediated by elevated levels of thyroid hormone. Anemia increases the need for cardiac output by reducing the oxygen-carrying capacity of a given quantity of blood. Many of the other conditions listed in Table III reflect disorders with arteriovenous fistulas, which shunt blood to the venous system without passing through the capillaries. Some dermatologic disorders, such as severe psoriasis, lead to a dramatic increase in skin blood flow, which is responsible for the increased need for cardiac output. In general, primary high-output failure is apparently uncommon. These and other causes of elevated cardiac output, however, should be considered as contributing or precipitating causes in patients whose ventricular reserve is reduced for other reasons.

Because coronary artery disease is the major cause of severe CHF in the U.S., it is worthwhile to comment further on the pathophysiologic mechanisms involved in producing CHF in this setting. Table IV lists the major factors that contribute to CHF in the presence of coronary artery disease. The first and most important is the loss of muscle because of myocardial infarction and subsequent scar formation. Reduction in the pumping ability of the heart and ventricular reserve naturally follow from reduction in the number of contractile elements. Ischemia is also an important way of reducing function. As angina or acute ischemia develops, there is an abrupt reduction in regional function, since ischemic muscle rapidly loses its ability to contract.[4] In patients with unstable angina, or occasionally with more chronic angina, restoration of blood supply by coronary bypass grafting results in improved regional wall motion, suggesting that more chronic ischemia can contribute to a reduction in ventricular function.[5]

Aneurysms can contribute to ventricular dysfunction in a number of ways. During the acute process of ischemia and infarction, ischemic muscle not only loses its ability to contract, but it invariably bulges paradoxically during systole. This paradoxical systolic expansion can reduce forward stroke volume as this portion of the ventricle accepts a volume of blood, depending on the size and compliance characteristics of the involved area. As the affected muscle passes through the necrotic to the healing stage, development of a fibrous scar reduces the compliance characteristics

of the aneurysm, so there is no longer the same degree of paradoxical systolic expansion. In vitro studies of aneurysmal tissue have pointed out the stiff character of ventricular aneurysms and the inability of fibrous tissue to stretch during systole.[6] The apparent paradoxical expansion occasionally seen on ventriculograms may represent stretching of surrounding muscle, which may be ischemic. Aneurysms also increase ventricular size, which may be adverse in increasing wall stress in the remaining normal muscle by the LaPlace relation.

Thus, reduction of ventricular size by aneurysmectomy may be an important means of reversing this detrimental effect of an aneurysm. When muscle is lost during an infarction, there is increased loading of the remaining normal muscle. In the same way that pressure or volume overload can eventually lead to an irreversible reduction in intrinsic contractility, it is likely that the same stresses may be operative in the normal muscle of patients with large myocardial infarcts.

One aspect of considerable interest in the patient with coronary artery disease is the decrease in ventricular compliance that appears to accompany the process of scar formation after infarction. Further, during acute angina pectoris, it appears that the ventricle becomes stiffer, presumably owing to some degree of ischemic contracture or relaxation abnormalities.[7] This tends to reduce ventricular filling and requires elevated filling pressures. For example, some patients with coronary disease have restriction of filling, rather than reduction in systolic function, as the primary mechanism for their pulmonary congestion.[8] Detrimental effects on both systolic and diastolic function, therefore, are caused by coronary disease and contribute to the heart failure syndrome.

Precipitating Events in Heart Failure

In trying to evaluate the cause of CHF in a patient, it is important to evaluate not only the underlying cause, but also the precipitating causes. The difference between worsening of the intrinsic CHF and superimposition of a precipitating cause is important in guiding therapy and determining prognosis. Many of the common precipitating causes are listed in Table V.

Reduction of therapy is one of the most common and important precipitating causes of CHF. Salt and dietary excesses are frequent causes for accumulation of extra fluid and worsening of CHF. Similarly, reduction or discontinuation of pharmacologic therapy, owing to poor compliance, running out of medications, etc, is a common cause that must be considered.

Arrhythmias can often aggravate, and in some circumstances precipitate, severe CHF. For example, the development of rapid supraventricular or ventricular tachycardia can worsen CHF dramatically in patients with reduced ventricular reserve. Viral or bacterial infections or superimposed pulmonary embolism are frequently responsible for worsening of the CHF state. Superimposition of physical, environmental or emotional stress also adversely affects the heart, presumably by increasing the demands on the heart in the setting of reduced ventricular reserve. Bacterial endocarditis, myocarditis and inflammation are obvious causes of worsening CHF. We have already discussed some forms of high-output CHF, which are more commonly manifested as precipitating causes of CHF. Finally, the development of unrelated illnesses or a second form of heart disease can also provoke worsening heart failure. For example, in the patient with valvular heart disease, the development of coronary artery disease can precipitate CHF and other cardiac events, because of the superimposed ischemia.

TABLE V Precipitating Causes of Congestive Heart Failure

Reduction of therapy
Arrhythmias
Systemic infection
Pulmonary embolism
Physical, environmental and emotional stress
Cardiac infection and inflammation
High output states
Unrelated Illness
Second form of heart disease

TABLE VI Myocardium in Congestive Heart Failure

1. Mechanical alterations
Decreased velocity of shortening
Decreased force development
Decreased maximum rate of force development
Little or no change in passive length-tension relations
No change in series elastic
2. Biochemical alterations
Decreased actomyosin ATPase activity
Increased collagen
Decreased myocardial norepinephrine
Decreased synthesis of norepinephrine
Decreased function of sarcoplasmic reticulum
? Decreased high-energy phosphates
? Excess myoplasmic calcium

Myocardial Contractility in Heart Failure

Let us now turn to some of the changes associated with a reduction in intrinsic contractility of the myocardium in CHF. In many circumstances, it is the intrinsic reduction in contractility that contributes primarily to the heart failure state, and that appears to be essentially irreversible. Table VI lists some of the mechanical and biochemical changes that have been noted. In vitro studies of the mechanics of myocardial contraction in animal models of heart failure have noted a variety of changes.[9] First, there is a decreased ability of failing muscle to develop force and to shorten with a given velocity at specified loading conditions. The decrease in velocity of shortening is conceptually related to the observed decrease in maximal rate of force development.

The elastic properties of failing heart muscle have also been examined in animal models of CHF. In general, there is little or no change in the passive length-tension relations of isolated failing heart muscle. Yet this does not obviate the fact that there can be dramatic changes in passive pressure-volume relations of the intact ventricle. Hypertrophy of the ventricle per se can

TABLE VII Hormonal Changes in Congestive Heart Failure

Increased circulating catecholamines
Increased renin-angiotensin-aldosterone
Increased arginine vasopressin

TABLE VIII Compensatory Mechanisms in Congestive Heart Failure That Can Overshoot

Excessive rise in preload
Excessive increase in systemic vascular resistance
Excessive increase in heart rate
Excessive increase in catecholamines
Excessive activation of renin-angiotensin-aldosterone system

produce dramatic changes in compliance, even though each unit of muscle may have relatively normal passive length-tension relations.[10] Another elastic property of muscle is the series elastic, which can be measured by quick release techniques during contraction. There does not appear to be any change in the series elastic properties of failing heart muscle,[11] which may reside primarily in the crossbridges.

Several biochemical alterations have been described during CHF, although it has been very difficult to determine any cause-and-effect relation between a given biochemical change and the heart failure state. That is, one cannot point to any single biochemical alteration as a cause for the reduction in intrinsic contractility. One of the more interesting changes is the decrease in actomyosin-ATPase activity.[12] At the crossbridge, actin-activated myosin has ATPase activity, which releases energy for contraction. Previous studies suggest that actomyosin-ATPase activity is related to velocity of shortening, an interesting correlation between muscle mechanics and biochemistry.[13] In CHF, there is a decrease in both velocity of shortening and actomyosin-ATPase activity. This is mediated by an alteration in myosin isozymes, with a shift from fast to slow isozymes. Thus, this shift in enzymatic activity is not only associated with a decrease in velocity of shortening, but also with a decrease in energy expenditure.[14] The decrease in oxygen consumption, therefore, may be of benefit to the heart if there is a limitation of oxygen supply, either because of hypertrophy or coronary artery disease.

During the process of hypertrophy and heart failure, increased myocardial collagen content has been observed.[15] This may be part of the hypertrophy process itself. Decreased stores of norepinephrine have been noted in some animal models of CHF.[16] This presumably reflects an increase in sympathetic tone and release of catecholamines in an attempt to maintain cardiovascular conpensation in the face of a decrease in contractility. In some studies, a decrease in synthesis of norepinephrine was also noted, because of a depression of the enzyme, tyrosine hydroxylase.[17] Decreased function of the sarcoplasmic reticulum has also been noted with a decreased rate of uptake of calcium and decreased stores of calcium.[18]

Initial studies of high-energy phosphates in CHF suggested that there was no reduction and concluded that depletion of high-energy phosphates could not adequately explain the CHF state.[19] More recent studies suggest that in some instances, there can be depletion of high-energy phosphates during CHF.[20] The cause-and-effect relation between these 2 factors, however, is not established. In some instances of CHF, such as that produced by ischemia or in the hereditary congestive cardiomyopathy of the Syrian hamster, excess calcium accumulation has been demonstrated as part of the CHF process.[21] Because excess calcium can produce a number of deleterious effects in the myocardium, including depression of mitochrondrial function, the pathophysiologic role of excess calcium deserves further study.

Peripheral Factors in Heart Failure

A number of hormonal changes occur in CHF, some of which are listed in Table VII. There are increased circulating catecholamine levels owing to an increase in sympathetic tone and release of catecholamines from the adrenal medulla. There is a general relation between the severity of CHF and the level of circulating catecholamines,[22] which presumably are designed to maintain cardiovascular function in the face of decreased intrinsic contractility. The renin-angiotensin-aldosterone system is also frequently activated. Angiotensin II has several potentially adverse effects in CHF. First, it is a potent vasoconstrictor, and thus may directly contribute to an excessive increase in systemic vascular resistance. Second, it facilitates sympathetic outflow, and therefore enhances levels of circulating catecholamines. Third, it leads to an increased release of aldosterone, which promotes further retention of salt and water. Certainly, the activation of the renin-angiotensin-aldosterone system sets the stage for the use of angiotensin converting enzyme inhibitors in CHF.[23]

Another vasoconstrictive hormone that is elevated in CHF is arginine vasopressin.[24] It is unclear how much this enzyme contributes to the elevated systemic vascular resistance seen in CHF, and further studies are needed to put the role of this hormone into better perspective.

One of the more interesting concepts developed over the past few years is that although compensatory mechanisms may be helpful in maintaining cardiac function, these mechanisms have the potential for overshooting and producing deleterious effects. Some of these compensatory mechanisms are listed in Table VIII. The retention of salt and water that occurs because of decreased cardiac output and renal perfusion can lead to an excessive increase in preload. Initially, an increase in preload is effective in increasing cardiac output through the Frank-Starling mechanism. As preload increases further, however, it leads to congestive symptoms without any further improvement in cardiovascular performance.

Evidence is convincing that systemic vascular resistance is often too high in the CHF state. This is part of the vicious cycle of heart failure. As cardiac output decreases, systemic vascular resistance increases through the potent neurohumoral reflex mechanisms that have been described. This increased resistance, however, can

further increase the resistance to ejection of blood, reduce cardiac output and therefore lead to a steady-state condition in which cardiac output is lower and systemic vascular resistance is higher than optimal for the patient. The best evidence to support this phenomenon is pharmacologic; i.e., potent arteriolar drugs can improve forward cardiac output in CHF without other major effects on hemodynamics.[25]

Heart rate is almost invariably increased in the CHF state, presumably reflecting an increase in circulating catecholamines and sympathetic tone. The increase in heart rate is certainly important in maintaining cardiac output in the face of a fixed, low stroke volume. Under certain circumstances, however, an excessive heart rate may be deleterious. For example, heart rate is directly linked to myocardial oxygen consumption, so that the higher the heart rate, the greater the need for coronary blood flow. Additionally, with increased heart rate, the diastolic time during which coronary flow occurs is shortened. Therefore, an increase in heart rate can not only increase demand, but can also potentially reduce supply, and thus adversely affect the patient with coronary artery disease. There may be adverse effects in patients with severe hypertrophy or cardiomyopathy.

In experimental animals, myocardial necrosis can be produced by massive infusions of catecholamines, such as isoproterenol.[26] It is unlikely that direct myocardial necrosis is produced in patients by an excess of catecholamines, although catecholamines can adversely affect patients in a number of ways. They produce an excessive rise in systemic vascular resistance, which can reduce cardiac output. Furthermore, they stimulate both heart rate and contractility and, therefore, contribute to an increase in myocardial oxygen consumption. If this occurs in the setting of reduced coronary reserve, the propensity for ischemia is considerable.

Although excessive activation of the renin-angiotensin-aldosterone system was already discussed, it is important to note that the initial effects of activation of this system may be beneficial, but can become deleterious in severe heart failure.

Therapeutic Approach to Heart Failure

By understanding the pathophysiologic mechanisms occurring in CHF, therapeutic solutions can be designed to each problem. This general approach is illustrated in Table IX, and will be briefly discussed. The increased preload or filling pressures of the right and left ventricles are responsible for the symptoms of pulmonary and peripheral congestion. A therapeutic goal is to reduce salt intake and use diuretics. In addition, venodilators are effective in reducing right- and left-atrial filling pressures by dilating peripheral veins and redistributing blood volume, with more in the periphery and less in the chest.[25]

The low cardiac output and accompanying high systemic vascular resistance seen in CHF are primarily responsible for the symptoms of fatigue, presumably caused by poor perfusion of skeletal muscle. Arteriolar dilators are effective in reducing systemic resistance and increasing forward cardiac output. This combination—decreasing an elevated preload and increasing a low cardiac output—represents the most important therapeutic hemodynamic goal in patients with CHF.[25]

TABLE IX Therapeutic Principles in Congestive Heart Failure

Problem	Therapy
Increased preload	Salt restriction, diuretics, venodilators
Low cardiac output, high systemic resistance	Arteriolar dilators
Decreased contractility	Positive inotropic agents
Rapid heart rate, atrial fibrillation, sinus tachycardia	Increase atrioventricular block, improve left ventricular performance (? β blockade)

The decrease in intrinsic contractility seen in the CHF state sets the stage for the use of positive inotropic agents. Digitalis is the most widely available oral agent, and appears to have modest beneficial effects on hemodynamics. A number of intravenous drugs are available, particularly in the catecholamine class, which can be effective in patients with severe, acute CHF. Some intravenous drugs, such as dobutamine, are reported to be effective when infused intermittently in patients with severe heart failure.[27] A variety of positive inotropic agents are being investigated, and most of them have peripheral vasodilating qualities. Certainly, the combination of peripheral vasodilation and increased contractility is an attractive one for a given agent in reversing some of the major pathophysiologic changes that occur in CHF.[28]

A rapid heart rate during CHF often signals the severity of the CHF state. There is speculation that the heart rate response may be too rapid in some patients, and may therefore become a compensatory mechanism that overshoots. Certainly in atrial fibrillation with a rapid ventricular response, this is the case. The therapeutic reduction of ventricular rate by atrioventricular block with drugs such as digitalis can be dramatically effective in helping such patients. This is particularly true for the patient with mitral stenosis, but is equally true for virtually all other patients. There is some debate as to whether or not a rapid sinus tachycardia, in and of itself, can be deleterious. Use of β-blocking drugs has been proposed for patients with congestive cardiomyopathy, particularly those who appear to have heart rates out of proportion to the severity of CHF.[29] Whether attempts to reduce heart rate directly with β blockade may be effective in certain groups of patients is not clear. One group that might benefit would be patients with severe coronary disease. These patients have excess catecholamine secretion with only moderate heart failure; thus, they can tolerate β-blocker therapy. In general, a rapid sinus tachycardia tends to abate as left ventricular performance improves by any of the interventions discussed. This presumably reflects a reduction in the sympathetic tone and circulating catecholamines that are affecting the SA node.

In summary, we have discussed the general changes occurring in the CHF state that determine the pathophysiology of this condition. Certainly, a better understanding of the pathophysiologic factors allows us

to approach the patient more rationally in terms of therapeutic regimens. It is clear that changes both in systolic and diastolic function can produce adverse effects on performance. It is also clear that appropriate correction of compensatory factors that may have overshot is a major goal of the current therapeutic approach to patients with severe CHF.

Neurohumoral Mechanisms Involved in Congestive Heart Failure

GARY S. FRANCIS, MD

Congestive heart failure (CHF) promotes an array of biologic changes that are largely designed to compensate for reduced flow. These include activation of the sympathetic nervous system and the renin-angiotensin system, as well as the release of arginine vasopressin. The ultimate expression of these compensatory mechanisms is heightened vascular tone, increased sodium and water retention and antidiuresis. The peripheral circulation is normally under the fine control of circulating and neuronally released moieties, which can directly or indirectly alter vascular tone. Angiotensin II appears to be a key element in this regard because of its multiple biologic activities. Direct arteriolar vasoconstriction, facilitation of norepinephrine release and stimulation of aldosterone are some of the activities that are likely to be of major importance in the syndrome of CHF. Therefore, it is not surprising that converting enzyme inhibitors have a growing role as treatment. Other pharmacologic agents that can reduce sympathetic tone by acting on presynaptic receptors are being developed. Selective dilation of certain vascular beds may be possible with agents designed to interact with vascular dopaminergic receptors. The mechanisms whereby circulating epinephrine and norepinephrine modulate norepinephrine release and vascular tone are beginning to be understood and likely involve presynaptic, postsynaptic and nonsynaptic vascular receptors. A better appreciation of the mechanisms involved in the fine control of the peripheral circulation should allow for more selective and more imaginative pharmacologic therapy for CHF.

(Am J Cardiol 1985;55:15A–21A)

Congestive heart failure (CHF) is a complex clinical syndrome that defies simple definition. The mechanisms underlying its pathophysiology are poorly understood and treatment is not uniform. Despite these uncertainties, new treatments continue to evolve. In the case of converting enzyme inhibitors, the long-term favorable effects of therapy confirm the suspicion that the renin-angiotensin-aldosterone system undoubtedly plays an important mechanistic role in CHF. Other vasoactive moieties, including plasma norepinephrine (NE) and arginine vasopressin (AVP), are also increased in CHF.[1] However, pharmacologic inhibition of NE[2,3] and AVP[4] as a form of treatment is more controversial and less well developed than the use of converting-enzyme inhibitors.

Early studies in patients with systemic hypertension and cirrhosis led to the belief that arginine vasopressin, aldosterone and angiotensin II are also important in the pathogenesis of CHF.[5] Likewise, it has been known for many years that the sympathetic nervous system is abnormal in CHF.[6] More recently the concepts of increased circulating norepinephrine,[7] reduced myocardial β-adrenergic receptor density[8] and reduced myocardial responsiveness to β-adrenergic stimulation[9] have offered new directions for research in CHF. This review presents an overview of the roles of the sympathetic nervous system and the renin-angiotensin-aldosterone system as well as arginine vasopressin in CHF and focuses on how such insight might be translated into more rational pharmacologic therapy.

Plasma Catecholamines, Renin Activity and Arginine Vasopressin

Congestive heart failure is characterized by high levels of circulating norepinephrine[10] and, in many cases, there is increased plasma renin activity (PRA)[10] and plasma AVP.[11] Plasma epinephrine is also sometimes increased, but this hormone is more often normal in the unstressed patient with CHF. Epinephrine, a true circulating hormone, is released from the adrenal medulla in response to stress. Norepinephrine, primarily

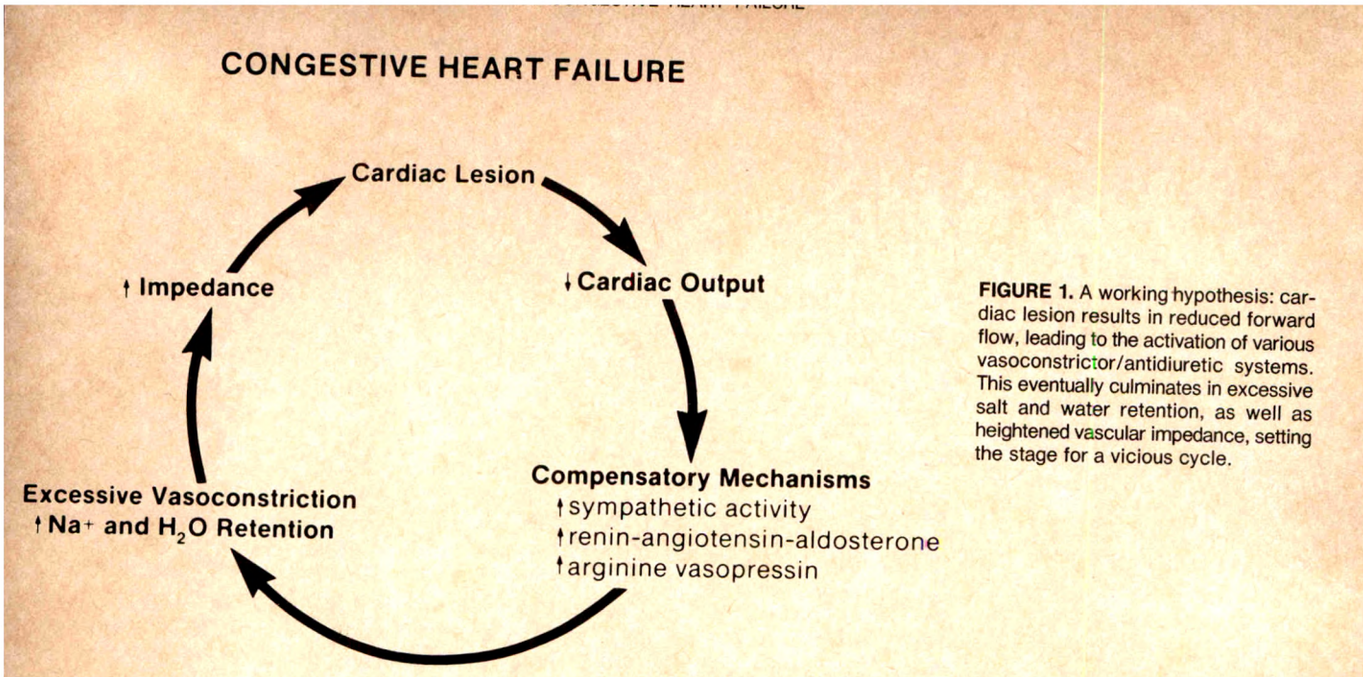

FIGURE 1. A working hypothesis: cardiac lesion results in reduced forward flow, leading to the activation of various vasoconstrictor/antidiuretic systems. This eventually culminates in excessive salt and water retention, as well as heightened vascular impedance, setting the stage for a vicious cycle.

a neurotransmitter, is not a circulating hormone, but is released from terminal sympathetic neurons during excitation of sympathetic nerves. It is generally agreed that venous plasma NE provides a useful index of average sympathetic nervous system activity.[12,13] What is not entirely clear is whether plasma NE, PRA and AVP actually contribute to the clinical syndrome of CHF in a biologically meaningful way. Do they offer support to the failing circulation or do they contribute a further burden to myocardium that is already operating inefficiently under an afterload stress (Fig. 1)?

The sympathetic nervous system and the endocrine system evolved as different systems devoted to coordination. The two systems overlap boundaries, although embryologically and phylogenetically they may have independent derivations.[14] It is presumed that sympathetic activity, PRA and AVP evolved as separate but interrelated functional units designed in part to maintain perfusion pressure and retain circulating volume in the face of inadequate blood flow.[15] The sympathetic nervous system, the renin-angiotensin system and AVP interact with each other. Angiotensin II, in addition to being an arteriolar constrictor and an important stimulus for the release of aldosterone, facilitates noradrenergic transmission in the autonomic nervous system.[16] Angiotensin II is also an acute stimulus for AVP release.[17] Arginine vasopressin potentiates the vasoconstrictor effects of NE and angiotensin II.[18] The hemodynamic effects of AVP are magnified when reflex control of the circulation is impaired,[19,20] and patients with CHF display a consistent abnormality of autonomic reflex control.[15] In normal unanesthetized dogs, arterial pressure does not increase substantially until plasma levels of AVP well in excess of the normal range are reached. In the absence of baroreceptor reflexes, the overall pressor sensitivity is enhanced 60- to 100-fold above normal.[21] Patients with CHF have a blunted baroreceptor response to upright tilt[22] and a reduced sinus node response to pressor injections.[23] They are perhaps more sensitive to increased circulating AVP, although this is still unproved. Reports comparing vasoconstrictor actions of various humoral agents indicate that AVP is the most potent circulating vasoconstrictor hormone studied to date.[24]

The precise signals that activate the sympathetic nervous system, the renin-angiotensin system and arginine vasopressin in CHF are unknown. They are probably under different control mechanisms, since the correlation coefficient between plasma NE and PRA in patients with heart failure is rather modest ($r = 0.38$).[10] The correlation between plasma AVP and plasma NE is also low ($r = 0.31$), as it is between AVP and PRA ($r = 0.53$).[11] Although these systems are probably under different control mechanisms, they facilitate each other's biologic activities and share the common properties of vasoconstriction and antidiuresis. This suggests that together they orchestrate a major defense system against inadequate perfusion from many causes, including inadequate cardiac output. The critical unanswered question is whether these systems act to "overcompensate" in CHF, resulting in circulatory congestion and heightened vascular impedance on a myocardium that is already operating under an imposed afterload stress. This may be the case, because inhibition of NE release by bromocriptine[25] and interruption of the renin-angiotensin system by converting-enzyme blockade[26] acutely improve the hemodynamic status of patients with CHF. As is often the case in clinical medicine, treatment may eventually yield further insight into mechanisms of the disease process itself.

Biosynthesis, Release and Biologic Activity of Norepinephrine—Vascular Neuroeffector Mechanisms and Interaction with Angiotensin II

Both the neurotransmitter norepinephrine and the hormone epinephrine are synthesized by chromaffin cells in the adrenal medulla and parts of the brain, whereas only NE is synthesized in the postganglionic

sympathetic nerves. The enzymes necessary to convert L-tyrosine to NE are present in the nerve ending, where the bulk of the NE is synthesized and stored (Fig. 2). Under normal circumstances L-tyrosine is transported from the blood across the membrane of the sympathetic nerves by a special concentrating mechanism. It is then acted upon by tyrosine hydroxylase to slowly produce L-dihydroxyphenylalanine (dopa). This is normally considered to be the rate-limiting step in the biosynthesis of NE.[27] Tyrosine hydroxylase activity is itself inhibited by NE, which is important in controlling NE synthesis.[28] Dopa is then rapidly decarboxylated in the terminal nerve to dopamine, which must then enter the small granulated vesicles, where it is finally hydroxylated by dopamine-β-hydroxylase (DBH) to NE. The NE is then stored until excitation of the sympathetic nerve results in exocytosis, a process whereby storage granules move, perhaps via microtubules, to the surface of the nerve membrane where they expel their contents into the synaptic cleft. Release of NE and DBH is enhanced by calcium ions and is inhibited to some extent by prostaglandin E_2. An important majority of the NE released by the nerve ending is taken back up into synaptic nerve terminals by active transport mechanisms (uptake 1). A lesser amount diffuses into the bloodstream, binds to postsynaptic receptors or is actively taken up by muscle tissue (uptake 2) and subsequently metabolized by catechol-o-methyl transferase and monoamine oxidase. The concentration of NE measured in plasma is therefore only a small fraction of what is released into the synaptic cleft, although it generally does reflect the amount of sympathetic activity.[13]

In patients with CHF[29] and in experimental animal models of heart failure,[30] the biosynthesis of NE is deranged. Patients with CHF have reduced myocardial stores of NE,[29] but may have increased myocardial dopamine content.[31] This is also true of certain animal models of heart failure. Syrian hamsters with hereditary cardiomyopathy cannot transfer dopamine efficiently across the membrane of the noradrenergic granule,[32] which could account for the 20-fold increase in dopamine content and the markedly reduced NE content of the myocardium in this model. This essentially shifts the rate-limiting step of NE biosynthesis from hydroxylation of tyrosine to the hydroxylation of dopamine. The mechanism of reduced transport of dopamine across vesicular membranes is uncertain, but could be due to an acid pH in the nerve terminal cytoplasm, allowing for protonation and subsequent poor membrane transportability of dopamine.[33] High-energy phosphate depletion could also account for this mechanism, because this transport is dependent on magnesium-activated adenosine triphosphate.[34]

The release of NE from postganglionic neurons is complex and incompletely understood. It is likely that many presynaptic receptors can facilitate or inhibit NE release. These include the presynaptic α_2 receptor, the presynaptic β_2 receptor, the presynaptic dopamine (DA_2) receptor, and the presynaptic angiotensin II receptor (Fig. 3). Although there is still controversy regarding the actual presence and activity of these various receptors on neurons, data have emerged that generally

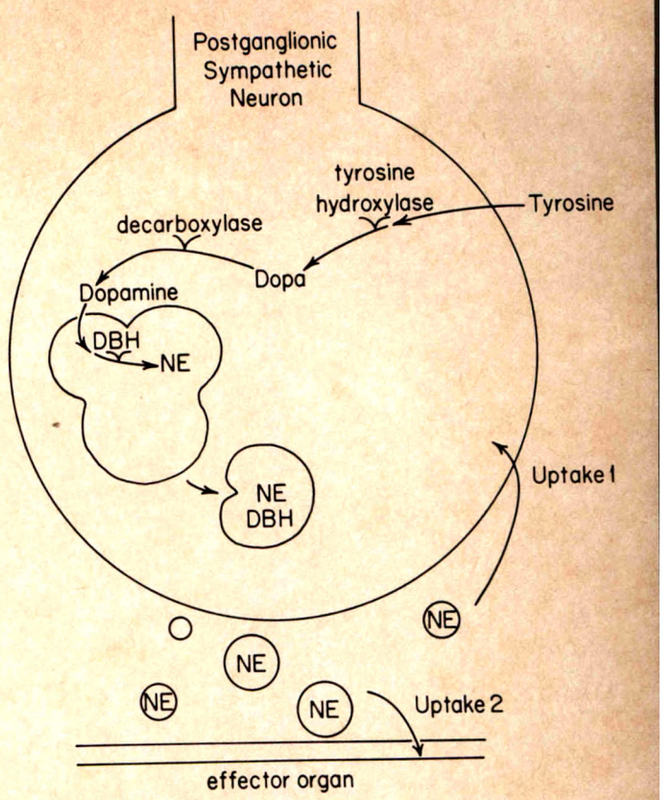

FIGURE 2. Biosynthesis, storage and release of norepinephrine (NE) from terminal sympathetic neuron. A potential lesion in heart failure may be the inability to transport dopamine from the cytoplasm to the vesicle, resulting in a reduced NE level and increased dopamine myocardial content. DBH = dopamine-β-hydroxylase.

support the concept of multiple controls over the release of NE from sympathetic nerves. Presynaptic α_2 receptors are believed to be located on membranes of sympathetic neurons.[35] When the presynaptic α_2 receptor is engaged by an endogenous agonist such as NE, or a pharmacologic agonist such as clonidine, guanabenz or guanfacin, NE release is inhibited.[36] With NE, this mechanism likely serves a negative feedback system that partially regulates sympathetic drive. Presynaptic neuronal β receptors are also likely to be present[37] and they appear to facilitate NE release when stimulated by an agonist such as epinephrine or NE.[38] The presynaptic β adrenoceptors are probably of the β_2 variety[39] and are therefore likely to be more responsive to epinephrine than NE. Like the presynaptic α_2 receptor, the presynaptic DA_2 receptor subserves inhibition of NE release from postganglionic sympathetic nerves in response to nerve stimulation.[40]

Although there are a large number of pharmacologic DA_2 agonists, the two that have been used to blunt high sympathetic drive in patients with CHF are bromocriptine[25] and propylbutyldopamine.[41] Bromocriptine inhibits NE release,[42,43] and this effect may be mediated through a central dopaminergic rather than a peripheral mechanism.[44] Angiotensin II receptors also occur on presynaptic sites where, like β receptors, they facilitate the release of NE.[45,46] In addition to presynaptic α_2, β_2, DA_2 and angiotensin II receptors, presynaptic inhibitory muscurinic and opiate receptors have also been

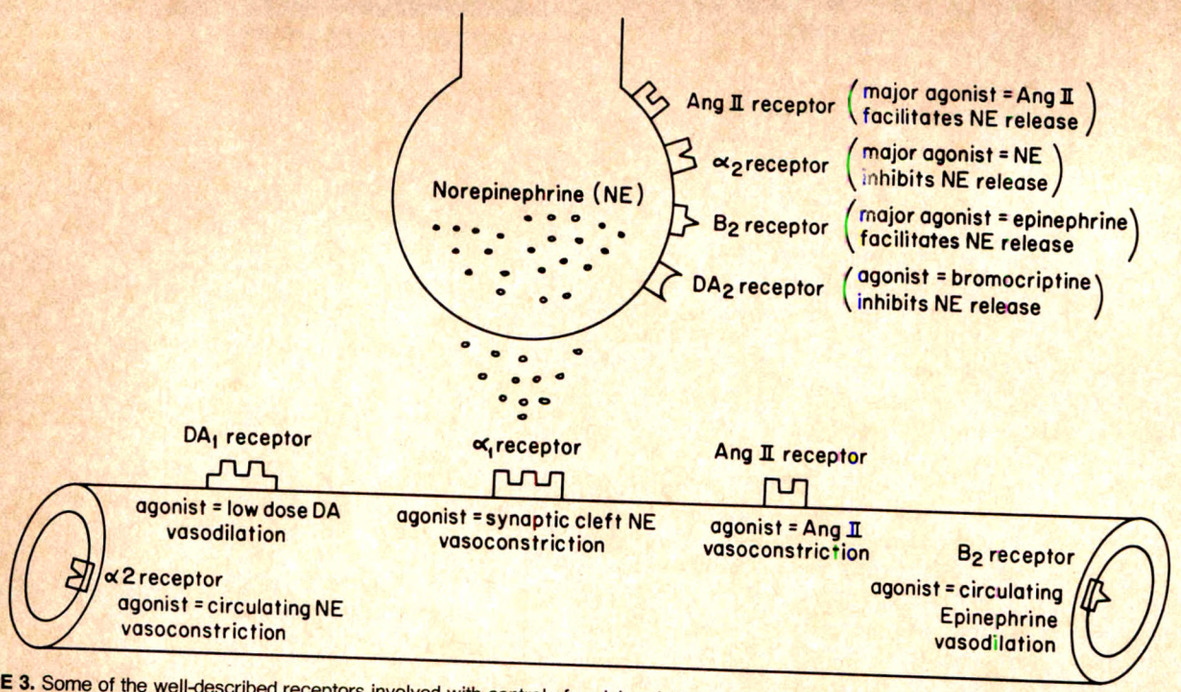

FIGURE 3. Some of the well-described receptors involved with control of peripheral circulation. Presynaptic DA_2 and α_2 receptors subserve inhibition of norepinephrine (NE) release, while presynaptic angiotensin II (Ang II) and β_2 receptors subserve facilitation of NE release. On the vascular side, postjunctional α_2 receptors are near the lumen and are sensitive to circulating catecholamines. They subserve vasoconstriction. Postjunctional β_2 receptors are similarly remote from the synaptic cleft and subserve vasodilation. The postsynaptic α_1 receptor responds to neuronal release of NE with vasoconstriction. Vascular DA_1 and angiotensin II receptors subserve vasodilation and vasoconstriction, respectively. The DA_1 receptor is responsive to circulating substances such as low-dose dopamine and SKF 82526.

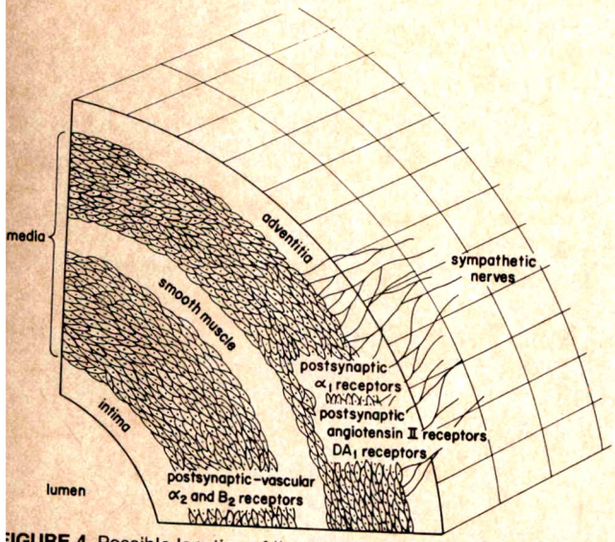

FIGURE 4. Possible location of "postsynaptic" vascular receptors that may be amenable to pharmacologic therapy in congestive heart failure. The vascular postjunctional α_2 and β_2 receptors are remote from the synaptic cleft and are likely more responsive to circulating or blood-borne catecholamines. Postsynaptic α_1 receptors are in close proximity to synaptic cleft and are responsive to neuronally released norepinephrine, resulting in vasoconstriction. Postjunctional α_2 receptor modulates vasoconstriction, and postjunctional β_2 receptor modulates vasodilation. The actual location of vascular angiotensin II receptors, which promote vasoconstriction, is not entirely clear. The precise location of extrajunctional DA_1 receptor, which produces vasodilation, is also not entirely clear, but it seems responsive to circulating or blood-borne low concentrations of dopamine, as well as to pharmacologic agent SKF 82526.

described.[47] Additionally, inhibition of NE release by prostaglandins of the E series may be linked to specific presynaptic receptors.[48] Metabolic changes in the vicinity of the adrenergic neuroeffector junction can also decrease the output of neurotransmitter, including adenosine, potassium, hyperosmolality and the hydrogen ion.[49] Knowledge of the interaction of these multiple presynaptic receptors and their modulator activity is obviously incomplete, but fine pharmacologic control of sympathetic tone by use of converting-enzyme inhibitors and selective DA_2 agonist may be useful to reduce the heightened sympathetic drive present in CHF. Such fine control may contribute to an improved clinical state.

At least 5 putative postsynaptic vascular receptors have been identified (Fig. 3), and information about them is rapidly increasing.[35] The postsynaptic α_1 receptor is sensitive to neuronally released NE and responds with vasoconstriction. It is present on both arterioles and veins, although deep veins in the skeletal muscles have little or no sympathetic innervation. The α_1 postsynaptic receptors are located in smooth muscle adjacent to nerve varicosities at the interface of the adventitia and the media (Fig. 4). The vascular α_2 receptors are located extrajunctionally, closer to the lumen, at some distance from the nerve terminal,[50] and are more responsive to exogenous or circulating epinephrine and NE.[35] The vascular α_2 receptors are present in both veins and resistance vessels and mediate vasoconstriction. Circulating epinephrine is slightly

more potent than NE at vascular α_2 receptors.[50] It is of interest that calcium antagonists cause a significant reduction of the vasoconstrictor response induced by selective vascular α_2 agonists.[51] Calcium entry blockers do not interfere with the formation of the vascular α_2-agonist/receptor complex, but they may prevent the influx of extracellular calcium ions associated with activation of the α_2 receptor. Some of the vasodilator properties of calcium blockers may be related to this mechanism. Vascular β adrenoceptors are similarly remote from the synaptic cleft and are also more sensitive to circulating rather than neuronally released catecholamines. The vascular β receptors modulate vasodilation rather than vasoconstriction. It is unclear if vascular β receptors are present on veins, but they have been convincingly demonstrated in arterial vessels,[52] where they are probably of the β_2 variety.[53] Vascular postsynaptic DA_1 receptors have been identified in the renal, mesenteric, coronary and cerebral circulations, where they are known to modulate vasodilation.[54] The DA_1 receptor agonist dopamine is sometimes clinically used in small doses to promote renal artery vasodilation and saluresis in patients with CHF. Preliminary data suggest that SKF 82526, an oral synthetic DA_1 agonist, may have potential use in CHF by increasing renal blood flow and enhancing natriuresis.[55] Smooth muscle arteriolar vasculature also contains postsynaptic angiotensin II receptors.[46] Angiotensin II interacts directly with this receptor to promote vasoconstriction. An adrenergic potentiating effect of angiotensin II on smooth muscle also appears to be attributable to a postsynaptic action.[56]

Angiotensin II, like NE, plays a pivotal role in control of peripheral circulation. Angiotensin II facilitates NE release through a presynaptic receptor mechanism, promotes vasoconstriction directly through a postsynaptic receptor, blocks neuronal uptake of NE,[57] enhances NE biosynthesis in the adrenergic nerve terminal,[58] releases epinephrine from the adrenal medulla,[59] acts on the adrenal cortex to release aldosterone, augments the vascular smooth muscle response to various agonists and probably stimulates central NE activity as well. Thus, it is not unexpected that in patients with CHF in whom the converting-enzyme activity is blocked, both sympathetic tone and salt and water retention are reduced. It is also possible that high concentrations of converting-enzyme inhibitor act directly to block the α-adrenergic responsiveness in vascular smooth muscle.[60] Converting-enzyme-inhibiting drugs, therefore, may act through multiple mechanisms in patients with CHF (Table I).

Several analogs of angiotensin II have been developed for diagnostic and therapeutic purposes,[61] including Sar^1 Ala^8 angiotensin II, which acts as partial competitive inhibitor or agonist at the postsynaptic vascular receptor site. When circulating levels of endogenous angiotensin II are elevated, Sar^1 Ala^8 angiotensin II will displace endogenous angiotensin II from the receptor, resulting in a net vasodilator antagonist effect. When receptor occupancy is low, such as during converting enzyme activity treatment, this analog acts as an agonist, mimicking the pressor effects of endogenous angiotensin II. Therefore, it could be used to treat severe hypotension resulting from excessive converting enzyme activity therapy.

TABLE I Potential Mechanisms of Converting Enzyme Inhibitors in Patients with Heart Failure

Inhibition of A_{II} formation resulting in arteriolar dilation
Inhibition of A_{II} formation resulting in reduced aldosterone production
Inhibition of A_{II} formation resulting in reduced NE release
Inhibition of A_{II} formation resulting in "densensitization" of vascular tissue to constrictor substances
Inhibition of A_{II} formation resulting in ↓NE biosynthesis
Inhibition of brain A_{II} formation resulting in ↓CNS sympathetic activity
Inhibition of A_{II} resulting in improved right ventricular-pulmonary vasculature compliance
Direct α_1 adrenergic vascular receptor blockade (requires large doses in vitro)
Increase in local prostaglandin production with venodilation

A_{II} = angiotensin II; NE = norepinephrine; CNS = central nervous system.

Although the preceding description of adrenergic and angiotensin receptor activity is undoubtedly oversimplified and subject to change, a basic understanding of these processes may be useful for clinicians caring for patients with CHF. Progress in the pharmacologic control of peripheral circulation is rapidly evolving, and future directions may include many different agents that can selectively activate or block various receptor activities. Table II lists what is known about the control of the peripheral circulation by certain receptors. Undoubtedly, other receptors responsive to acetylcholine, serotonin, AVP and others are also important in this regard, but their pharmacologic control has not been explored in CHF.

Arginine Vasopressin in Congestive Heart Failure

Until recently, the antidiuretic hormone AVP has not been well studied in patients with CHF, in part because of the lack of reliable assay techniques. An early report using a bioassay did suggest, however, that vasopressin may sometimes be abnormally increased in patients with CHF.[62] The availability of a sensitive and specific radioimmunoassay with an intraassay coefficient of variation of less than 4% has allowed investigators to detect changes in plasma vasopressin as small as 0.2 pg/ml.[63] Although the increase in circulating AVP in patients with CHF is neither as uniform nor as striking as that of plasma NE and PRA, on average there is about a 2-fold increase in circulating AVP in most patients.[11] The precise mechanism of increased AVP in heart failure, as with plasma NE and PRA, is not well understood. Increased angiotensin II could stimulate release of AVP,[17] but as previously noted, the correlation between PRA and AVP is only modest ($r = 0.53$). Moreover, captopril given acutely fails to lower AVP in patients with CHF.[11] Digitalis therapy, if it had any effect, would tend to lower AVP levels.[64] AVP may not be cleared adequately by the liver and kidneys in patients with CHF, but an increase in levels is observed even in patients who demonstrate normal hepatic and renal function.[11] Abnormalities of osmotic control are more likely to be involved, because patients with CHF

TABLE II Neuronal and Vascular Receptors Linked to Control of the Peripheral Circulation

Receptor	Location	Agonist	Antagonist	Biological Activity	
				Agonist	Antagonist
α_2 adrenergic	Neuronal (central, peripheral)	NE Clonidine Guanabenz Guanfacin α-methyldopa metabolite	Yohimbine Rauwolscine	↓NE release	↑NE release
α_2 adrenergic	Vascular	Epinephrine NE (circulating)	? Calcium channel blockers (indirect)*	Vasconstriction	Vasodilation
DA_2	Neuronal (central, ganglionic, peripheral)	Dopamine Bromocriptine Propylbutyldopamine	Metaclopramide S-sulpiride	↓NE release ↓Prolactin	Antiemetic
DA_1	Vascular (renal, mesenteric, coronary, cerebral)	Dopamine (small dose) SKF 82526	R-sulpiride Haloperidol	Vasodilation Natriuresis	
α_1 adrenergic	Vascular	NE (neuronal)	Prazosin	Vasoconstriction	Vasodilation
Angiotensin II	Neuronal	Angiotensin II	Converting enzyme inhibitors (indirect)*	↑NE release	↓NE release
Angiotensin II	Vascular	Angiotensin II	Saralasin (partial agonist)	Vasoconstriction	Vasodilation
β_2 adrenergic	Neuronal	Epinephrine NE	Propranolol Timolol	↑NE release	↓NE release
β_2 adrenergic	Vascular	Epinephrine NE (circulating) Dobutamine	Propranolol Timolol	Vasodilation	Vasoconstriction

* Calcium channel blockers and converting-enzyme inhibitors do not interact directly with α_2 receptors and therefore are not α_2 receptor "antagonists" in the usual sense. See text for explanation.
NE = norepinephrine.

lack the usual good correlation between serum sodium and AVP. Low serum sodium may coexist with high AVP levels in patients with CHF, but increased vasopressin does not always result in hyponatremia. We have observed that these patients do not suppress their AVP with water loading to the same extent as normal subjects do. In the absence of frank hypotension, a reduction in filling pressure with nitroprusside fails to stimulate AVP in heart failure, suggesting that intracardiac baroreceptor reflexes are not very important in the fine-control mechanisms of AVP release. Despite our uncertainty regarding the mechanism of AVP increase in patients with CHF, we believe that it may be contributing to heightened vascular resistance and water retention. The development of selective blockers of the vascular and renal effects of vasopressin may allow this hypothesis to be tested.

In conclusion, treatment for patients with CHF is rapidly evolving. Important new information about the mechanism of peripheral vascular control has led to the belief that fine control of these systems may be possible. The development of the converting-enzyme inhibitors is an excellent example of how basic science can quickly translate into established treatment when the need is pressing. Perhaps more importantly, a firmer understanding of the control of peripheral circulation has been made possible by the work of many basic pharmacologists and clinical investigators. The era of simply prescribing a "vasodilator" for CHF is over. Highly selective agents with the potential for much finer control of circulation will become available. The use of such selective agents may not only result in more rational treatment for CHF, but may ultimately expand our understanding of some very basic processes related to control of peripheral circulation.

Cardiopulmonary Exercise Testing for Evaluation of Chronic Cardiac Failure

KARL T. WEBER, MD, and JOSEPH S. JANICKI, PhD

The heart, lungs and hemoglobin form the body's gas transport system, which links the atmosphere and its supply of O_2 with tissue, while simultaneously providing for the elimination of the metabolic end-product, CO_2, into the atmosphere. The transport of these respiratory gases must be in accordance with metabolic need. This is particularly evident during the physiologic stress of isotonic exercise, when the O_2 requirements and CO_2 production of skeletal muscle are increased. The monitoring of these respiratory gases during exercise, referred to as cardiopulmonary exercise testing (CAR-PET), can be used to assess heart and lung function in patients with cardiovascular or lung disease or both. Chronic cardiac failure (CCF) may be defined in physiologic terms as that circumstance in which the heart fails to provide tissue with O_2 at a rate commensurate with aerobic requirements. In patients with CCF, CAR-PET represents a noninvasive means to determine aerobic capacity (that is, maximal O_2 uptake) and anaerobic threshold during incremental treadmill exercise. It can also provide an objective measure of the severity of failure, the functional status of the patient and the heart's pump reserve. By using additional measurements of ventilation, arterial O_2 saturation and, in selected cases, hemodynamic monitoring, the nature and severity of cardiovascular and pulmonary disease may be evaluated.

(Am J Cardiol 1985;55:22A–31A)

The severity of chronic cardiac failure (CCF) has traditionally been gauged according to the extent of breathlessness or fatigue, or both, and the extent to which these symptoms limit effort tolerance. In an attempt to overcome such subjective and therefore frequently unreliable information, various expressions of ventricular function have been used. However, the relation between effort tolerance and such measurements as ejection fraction, cardiac output and left ventricular filling pressure, each of which is obtained in the resting state, is poor.[1–6] Similarly, the heart's pumping reserve, or maximum cardiac output, which reflects the severity of CCF in physiologic terms, cannot be predicted from these measurements of ventricular function.[5,7] A more reliable and objective estimate of patients' functional status and pump reserve is needed.

Determination of a patient's aerobic capacity and anaerobic threshold by the noninvasive measurement of respiratory gas exchange during incremental treadmill exercise provides such information.[5] In addition, it identifies aerobic and anaerobic levels of work for each patient. Combined with the measurement of air flow, this approach can be used to distinguish ventilatory from circulatory causes of exertional dyspnea.[8] Over the years we have relied heavily on this approach, which we term cardiopulmonary exercise testing (CAR-PET), for 3 purposes: to examine the severity of CCF, to determine the efficacy of various therapeutic interventions in patients with CCF,[9–12] and to evaluate the pathophysiologic responses associated with the appearance of exertional dyspnea or fatigue. In selected patients, we also monitor arterial O_2 saturation or intravascular hemodynamics, or both, to elucidate the pathophysiologic mechanisms of effort intolerance.[5,8,13] This report discusses CAR-PET and identifies how this relatively new approach can assist cardiologists in the evaluation and management of CCF.

The Physiologic Basis of CAR-PET

The body's gas transport system—the cardiopulmonary unit: The chemical source of energy that allows cells to derive the means necessary to sustain their many functions, including life itself, is the oxidation of carbohydrates and fats. Oxidation is the biochemical process by which electrons, derived from the breakdown of glucose and fats, are transferred from

hydrogen to O_2 to form water. Oxygen is the final acceptor of these electrons. It is therefore critical that the cells be linked to the atmosphere and its supply of O_2 to sustain oxidative metabolism. The heart and lungs, together with hemoglobin, form the body's gas transport system. At the same time that oxidative metabolism consumes O_2 ($\dot{V}O_2$), CO_2 is being produced ($\dot{V}CO_2$). The amount of CO_2 produced by oxidation is considered the *metabolic* source of CO_2[14] and is a function of the proportion of carbohydrates and fats utilized by the cells. Normally, 75 to 80 ml of CO_2 are produced for every 100 ml of O_2 consumed. The ratio of $\dot{V}CO_2$ to $\dot{V}O_2$ is termed the respiratory gas exchange ratio (R); R normally equals 0.75 to 0.80. Because an acidosis will occur if CO_2 accumulates in the body, the cells must again be linked to the atmosphere to provide for CO_2 elimination. The heart and lungs provide for CO_2 transport and its elimination into the atmosphere. Accordingly, the heart and lungs may be viewed as an integrated, metabolic unit designed to maintain O_2 and CO_2 transport and exchange; neither organ can function independently in meeting this objective. We term this respiratory gas transport system the "cardiopulmonary unit."[15]

The cardiopulmonary unit is placed under a considerable demand during isotonic exercise as the $\dot{V}O_2$ of exercising muscle and the $\dot{V}CO_2$ rise in proportion to the level of muscular work performed. O_2 availability must be matched to $\dot{V}O_2$. The integrity of the unit and the precision with which the heart and lungs provide O_2 and eliminate CO_2 can therefore be scrutinized during exercise. A defect in heart or lung function may first become apparent during the physiologic stress of exercise. Hence, in physiologic terms, CCF may be defined as that condition in which the heart cannot provide O_2 to tissue at a rate commensurate with aerobic requirements. In patients with severely advanced heart disease, CCF may be apparent at rest when $\dot{V}O_2$ is only 1 metabolic equivalent (3.5 ml/min/kg of dry body weight). With less severe disease, the defect in O_2 delivery may only become apparent as $\dot{V}O_2$ rises during physical activity.[16]

Years ago, the late Louis N. Katz[17] emphasized that the heart's inability to deliver O_2 could be secondary to a variety of disorders, and thus one must distinguish the cause. Cardiac output, for example, could be inadequate because of a *myocardial* defect (e.g., myocardial infarction or cardiomyopathy) or a nonmyocardial or *circulatory* cause (e.g., hypovolemia, mitral stenosis, occlusive pulmonary vascular disease or constrictive pericarditis). In this review we discuss patients with chronic cardiac failure, secondary to coronary heart disease or dilated cardiomyopathy.

Concepts of O_2 delivery and O_2 utilization: O_2 delivery in ml/min is the rate at which O_2 is transported to the tissues. O_2 delivery is equal to the product of cardiac output and the arterial O_2 content, and O_2 content is related to the concentration of hemoglobin, its degree of O_2 saturation and its O_2 combining capacity. The normal arterial O_2 content is 19 ml/100 ml, or 14 g/100 ml · 95% · 1.34 ml/g. A certain amount of the O_2 delivered to the capillaries is extracted by tissue. O_2 extraction is therefore expressed as the ratio of the arteriovenous O_2 difference to the arterial O_2 content. Because the amount of hemoglobin in venous blood is essentially no different from arterial blood, the amount of O_2 that leaves the capillaries will be represented by the O_2 saturation of venous blood. Therefore, venous O_2 saturation is a function of O_2 delivery and O_2 extraction. In the mixed venous blood of the pulmonary artery, O_2 saturation is a function of systemic blood flow and the body's overall extraction of O_2.

Oxygen delivery and O_2 extraction will be related to O_2 utilization, or the rate of O_2 consumption per unit time. To simplify this relation (i.e., by factoring out arterial O_2 content), $\dot{V}O_2$ is equal to the product of cardiac output and the arteriovenous O_2 difference. This is another version of Adolph Fick's theorem. At rest, $\dot{V}O_2$ averages 245 ml/min for a 70-kg person while O_2 delivery equals 950 ml/min (i.e., 5,000 ml/min of blood flow · 19 ml/100 cc of blood). Thus, there is more than an adequate supply of O_2 to satisfy $\dot{V}O_2$; as a result, systemic O_2 extraction averages 25%.

Cardiopulmonary and tissue reserves: The $\dot{V}O_2$ of the body's organs varies widely and differs from the percentage of systemic blood flow they receive. Moreover, the need for O_2 varies among tissues throughout the day according to physiologic priorities (e.g., walking, digestion, sweating). The heart and lungs must be able to respond to each of these demands and ensure O_2 transport relative to need. During muscular work, for example, $\dot{V}O_2$ increases. Minute ventilation ($\dot{V}_E$) and O_2 delivery must each increase proportionately and at a rate appropriate to sustain oxidation metabolism. With strenuous work, $\dot{V}_E$ increases to 8 times or more its level at rest. Rarely does $\dot{V}_E$ pose a limitation to sustaining aerobic work.[18] The ventilatory reserve available for exercise is reflected in the maximum voluntary ventilation (MVV) and the forced vital capacity (FVC) measured during routine pulmonary function testing. Exercise $\dot{V}_E$ constitutes some fraction of the MVV, while the exercise tidal volume occupies some fraction of the FVC. Normally, less than 50% of the MVV and FVC is used to respond to the ventilatory requirements of light, moderate and moderately heavy workloads.[19]

The heart's pump reserve is not as great as its ventilatory reserve. In an untrained person cardiac output will rarely increase more than 4- or 5-fold above its rest value with strenuous work. Thus, unlike the lungs, the heart poses a limitation to aerobic work. The final reserve to gas transport exists within the tissue and is related to its ability to raise the level of O_2 extraction and to vasodilate the circulation. This represents the tissue reserve. Together, the response in cardiac output and the ability of muscle to extract O_2 and vasodilate determine a person's aerobic capacity, or maximal $\dot{V}O_2$ ($\dot{V}O_2$ max).[20] $\dot{V}O_2$ max can therefore be equated to maximum O_2 delivery and maximum O_2 extraction. In the averaged-sized, middle-aged person, whose maximal cardiac output is 20 liters/min and whose maximum level of O_2 extraction is 75%, representing an arteriovenous O_2 difference of 14 ml/100 ml, $\dot{V}O_2$ max equals 2,800 ml/min or 40 ml/min/kg. $\dot{V}O_2$ max varies according to sex, age and physical training.[21] Furthermore,

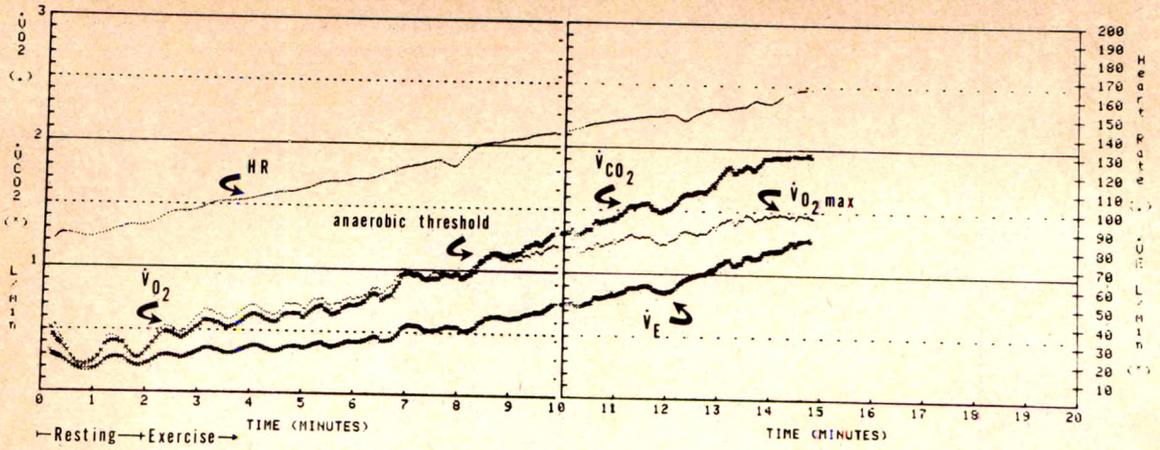

FIGURE 1. Breath-by-breath response in O_2 uptake ($\dot{V}O_2$), CO_2 production ($\dot{V}CO_2$) and minute ventilation ($\dot{V}_E$) to incremental (2-minute stages) treadmill exercise in a 65-year-old man with enlarged heart and mitral valve incompetence. Appearance of anaerobic metabolism is indicated by crossover in $\dot{V}O_2$ and $\dot{V}CO_2$; the corresponding $\dot{V}O_2$ is termed anaerobic threshold. Maximal O_2 uptake ($\dot{V}O_2$ max) is achieved when $\dot{V}O_2$ fails to increase more than 1 ml/min/kg after an increment in treadmill work. Heart rate (HR) response is also shown.

the $\dot{V}O_2$ max achieved for a particular muscle group or for a specific form of exercise should not be compared to other muscle groups or other forms of physical activity.[22] Treadmill exercise, for example, yields the largest $\dot{V}O_2$ max in normal subjects; thus, it should not be compared to the $\dot{V}O_2$ max measured during exercise on a bicycle ergometer or with arm exercise.

Muscular work and $\dot{V}O_2$ may increase more quickly or to the extent that the cardiocirculatory system can provide adequate O_2. Consequently, O_2 availability will be inadequate. In such cases, working skeletal muscle will resort to less efficient, anaerobic pathways to derive its energy. Anaerobic muscle produces lactate, which, because of its low dissociation constant, is rapidly buffered by bicarbonate. As a result of lactate buffering, an additional, *nonmetabolic* source of CO_2 is produced and R must rise above 0.75–0.80.[14] To maintain eucapnia under these circumstances, $\dot{V}_E$ must also increase. These variations in respiratory gases and $\dot{V}_E$ can be used to detect the onset of anaerobic metabolism during isotonic exercise and corresponding level of work, or $\dot{V}O_2$ associated with anaerobiosis. This event is termed the "anaerobic threshold."[23]

Types of CAR-PET

Noninvasive incremental treadmill exercise test: The availability of rapidly responding O_2 and CO_2 analyzers has made it possible to monitor these 2 respiratory gases on-line throughout exercise. These measurements, together with measurements of respiratory air flow, allow noninvasive determinations of $\dot{V}O_2$, $\dot{V}CO_2$, $\dot{V}_E$, respiratory rate and tidal volume in response to isotonic muscular work. The heart rate, electrocardiogram and cuff blood pressure should also be monitored, as is the standard practice in cardiology.

We chose a program of gradually progressive (2-minute stages), upright, treadmill exercise[9] for our patients with CCF. We did so because walking represents a nonspecialized skill that is easily negotiable, reproducible and reliable; at the same time, walking works a muscle mass large enough to stress the cardiopulmonary unit. By monitoring respiratory gas exchange and air flow we can determine the anaerobic threshold and $\dot{V}O_2$ max of these patients during a single exercise test.[5] We define $\dot{V}O_2$ max as $\dot{V}O_2$ remaining invariant (≤1 ml/min/kg) despite an increment in workload sustained for 30 seconds or more. Anaerobic threshold has been defined according to several criteria, including disproportionate increase in $\dot{V}CO_2$, $\dot{V}_E$ and R relative to $\dot{V}O_2$ and disproportionate rise in end tidal O_2 relative to end tidal CO_2. Figure 1 depicts the $\dot{V}O_2$ max and anaerobic threshold for a 65-year-old man with a dilated heart and mitral valve incompetence. We do not attempt to define the absolute time in which anaerobiosis occurs; only the stage of exercise and the corresponding level of work. We have found that $\dot{V}O_2$ max and anaerobic threshold are reproducible in these patients and that the anaerobic threshold occurs at approximately 60% or more of their aerobic capacity.[5] Over the past 10 years we have safely and reliably obtained this information in hundreds of patients with CCF, and in many of these patients the test has been performed serially over several years to monitor the natural course of their disease or their response to medical therapy. We have specifically excluded testing patients with aortic stenosis, exertional angina, significant arrhythmia or exercise-induced arrhythmia.

Finally, an indirect, noninvasive method of monitoring arterial O_2 saturation, the ear oximeter, can be used as part of this test. This is a particularly useful screening procedure in cases where O_2 desaturation might be anticipated (e.g., restrictive lung disease or pulmonary vascular disease). We find that patients with CCF do not have a significant fall in O_2 saturation during exercise.[5] The technique, however, can give erroneous information in the black patient because of pigmented skin. In cases where O_2 desaturation is suspected or evident from noninvasive monitoring, arterial O_2 saturation should be measured directly.

Invasive incremental treadmill exercise test:

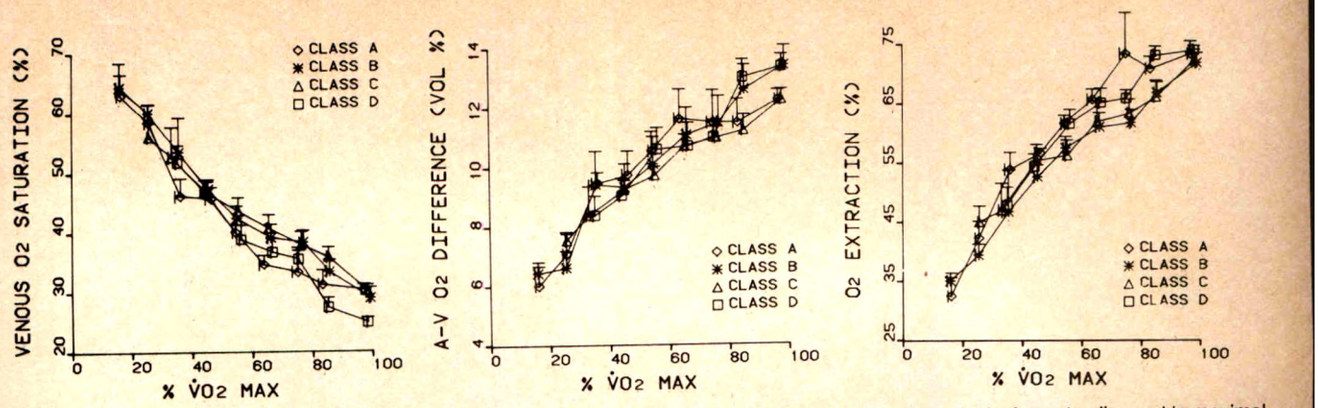

FIGURE 2. Response in mixed venous O_2 saturation, arteriovenous (A-V) O_2 difference and O_2 extraction, respectively, from standing rest to maximal exercise as a function of the normalized aerobic capacity (% $\dot{V}O_2$ max) for class A to D patients with chronic cardiac failure. Values of these parameters, observed for standing rest, are slightly different from those usually seen in supine rest and can be explained by reduction in cardiac output that occurs in standing position.

When myocardial failure needs to be differentiated from circulatory failure or when the severity of mitral apparatus dysfunction needs to be assessed, we monitor both the hemodynamic response and the gas exchange response to upright treadmill exercise.[5] For this test a triple-lumen flotation catheter with thermister is advanced via an arm vein into the terminal portion of the pulmonary circulation to obtain pulsatile pulmonary artery and occlusive wedge pressures with minimal catheter whip during each stage of exercise. Right atrial pressure can be similarly obtained through the proximal port of the catheter. We can also sample mixed venous blood for its O_2 saturation, and subsequently determine cardiac output by Fick principle and lactate concentration at each stage of exercise. Cardiac output by the thermodilution principle can also be determined during each stage. Advances in fiberoptic technology now make it possible to monitor mixed venous O_2 saturation on a continuous basis with a flotation catheter.[24] Finally, a catheter inserted into the radial or brachial artery of the same arm permits us to monitor arterial pressure directly and to sample arterial blood for its O_2 saturation and CO_2 tension if desired.

The Noninvasive Incremental Exercise Test in Evaluating the Severity of CCF

Maximum O_2 uptake: As noted earlier, $\dot{V}O_2$ max is a function of the maximum cardiac output that the heart can generate and the maximal amount of O_2 that the tissue can extract. We have assigned the aerobic capacity observed during an incremental treadmill exercise test into one of 4 classes, each of which represents a given degree of impairment.[5]

We termed the classes A, B, C and D to avoid confusion with the New York Heart Association classification.

Functional class A represents little or no impairment in aerobic capacity and is present when $\dot{V}O_2$ max exceeds 20 ml/min/kg. For age- and sex-corrected $\dot{V}O_2$ max of the normal adult population commonly seen in practice, $\dot{V}O_2$ max will be above this level. *Class B* represents mild-to-moderate impairment and is present when $\dot{V}O_2$ max ranges from 16 to 20 ml/min/kg. *Class C* represents moderate-to-severe impairment, and is present when $\dot{V}O_2$ max falls between 10 and 15 ml/min/kg. *Class D* represents a severe impairment, with a $\dot{V}O_2$ max of <10 ml/min/kg. The duration of treadmill exercise is far less precise in characterizing aerobic capacity and suffers from lack of an objective, quantitative endpoint to predict aerobic capacity. The predicted maximum heart rate is also imprecise in predicting $\dot{V}O_2$ max.[25] Moreover, exercise time is clouded by patient and physician bias. Finally, $\dot{V}O_2$ max correlates poorly with the New York Heart Association classification,[5] again emphasizing the subjective nature of clinical information.

To determine if impairment in aerobic capacity in patients with CCF is due to a compromised cardiac output response to exercise, inability of the tissues to extract O_2, or both, we monitored the response in mixed venous O_2 saturation, cardiac output, intravascular pressures and respiratory gas exchange during incremental treadmill exercise in 76 patients with CCF of varying severity (6 class A, 11 class B, 25 class C and 34 class D). Figure 2 shows the response in mixed venous O_2 saturation (SvO_2) from standing rest to maximum exercise in all classes of patients. We normalized $\dot{V}O_2$ at rest and during exercise according to $\dot{V}O_2$ max; i.e., each aerobic capacity was set equal to 100% and values less than $\dot{V}O_2$ max are equal to some fraction of the maximum. From its standing resting value, SvO_2 follows a common course, becoming progressively lower as O_2 extraction increases with higher workloads. At $\dot{V}O_2$ max, SvO_2 is 30% or less and there are no differences among classes. The same response, of course, is true for arteriovenous O_2 difference, which rises to 12 ml/100 ml or greater at maximal exercise and corresponds to an O_2 extraction in excess of 70% in each class. These data indicate that O_2 extraction increases progressively throughout exercise. The measurement of O_2 saturation and O_2 content in the femoral venous circulation of exercising leg indicate that O_2 extraction actually exceeds 80%.[26] The lesser value for O_2 extraction noted in mixed venous blood represents the dilutional effect of venous blood from other less active tissues (e.g., the splanchnic and cutaneous circulations). Thus, O_2 ex-

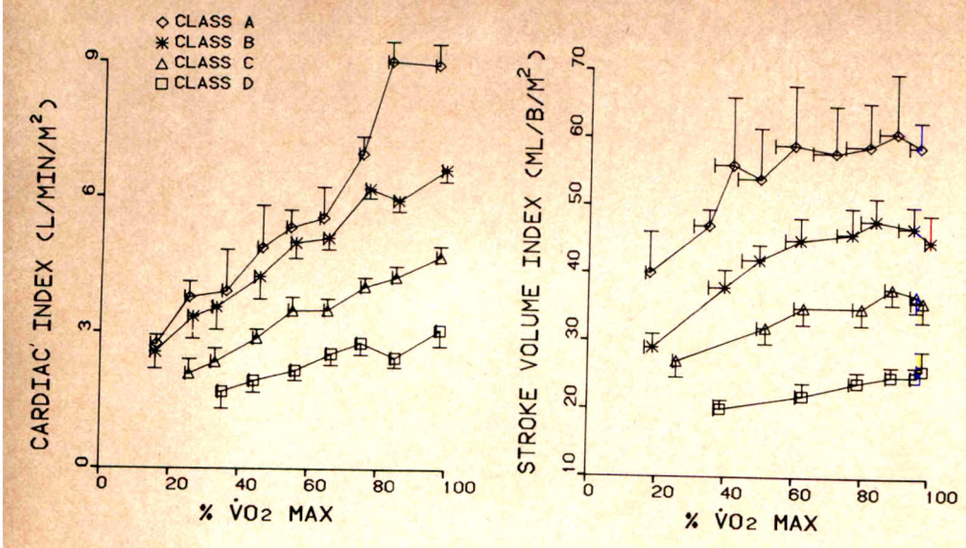

FIGURE 3. Response in cardiac output and stroke volume from standing rest to maximal exercise for each functional class. $\dot{V}O_2$ MAX = maximal oxygen uptake.

traction proceeds to maximal physiologic levels, while the absolute level of blood flow to the exercising limb may be less in patients with CCF.[26] Moreover, the ability of their skeletal muscle circulation to autoregulate may also be impaired.[27]

Given that O_2 extraction by muscle is not impaired, the reduction in aerobic capacity of these patients must therefore be primarily due to the heart's inability to sustain systemic blood flow according to the aerobic requirements of muscle. This is shown in Fig. 3, left, where the response in cardiac output to progressive isotonic exercise is given for each functional class. The resting cardiac output was not significantly different for classes A and B, while it was significantly different for classes B, C and D. At peak exercise the cardiac output was significantly different for each class. Thus, it is the heart's pumping reserve that is primarily responsible for the different aerobic capacities of these patients. Therefore, the $\dot{V}O_2$ max determination is a valuable noninvasive measure of pump reserve and can be used to predict the maximum cardiac output to exercise. Moreover, it can distinguish defects in pump reserve that are not apparent at rest (e.g., between classes A and B).

The cardiac output response to exercise for each class is a function of the heart's ability to raise its stroke

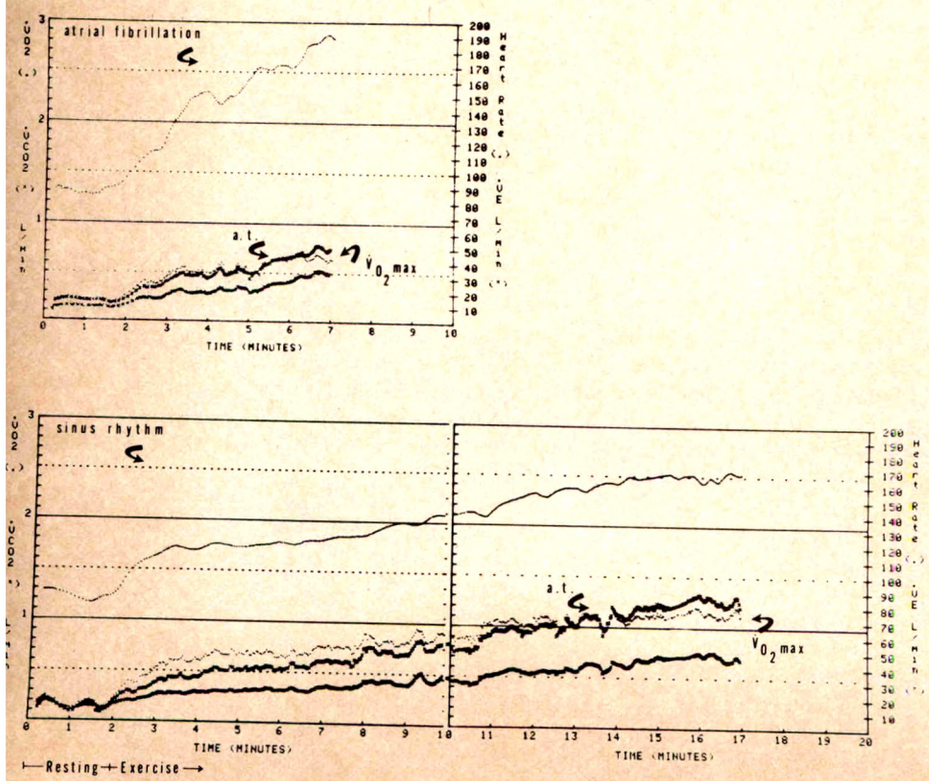

FIGURE 4. Response to isotonic exercise in a 32-year-old woman with mitral stenosis. **Upper tracing,** when the patient had atrial fibrillation and rapid elevation in heart rate during low levels of work, there was significant impairment in aerobic capacity, compatible with functional class D. Note early appearance of anaerobic threshold (a.t.). **Lower tracing,** aerobic capacity was significantly improved to class B, with return to sinus rhythm and more appropriate elevation in heart rate. $\dot{V}O_2$ and $\dot{V}CO_2$ = O_2 uptake and CO_2 production, respectively.

volume and heart rate. In class A and B patients, stroke volume rises during lighter workloads that represent less than 60% of $\dot{V}O_2$ max (Fig. 3); thereafter, stroke volume remains invariant. This response resembles that seen in normal subjects during upright exercise. In class C patients the improvement in stroke volume during the transition from rest to submaximal exercise is modest, whereas in class D, stroke volume does not vary throughout exercise. The most likely explanation for this impairment in stroke volume response is poor myocardial function. In addition, however, as venous return increases during exercise, the pericardium may restrain ventricular filling in these chronically dilated hearts.[28]

In each class the maximal heart rate response to exercise is a function of the maximal workload attained.[5] As a result, maximal heart rate is significantly different for each class. In class D patients, the elevation in heart rate is the sole mechanism by which cardiac output is increased. These observations, which indicate that the increment in heart rate is a function of workload, are contrary to traditional teaching, which suggests that a more dramatic increase in heart rate should occur in class D patients.[29] This latter view, however, is based largely on findings in patients with mitral stenosis and atrial fibrillation. With normal sinus rhythm, this is not the case. Figure 4 illustrates this point in a 32-year-old woman with mitral stenosis. Her exercise response is shown on 2 occasions: when she had atrial fibrillation and a rapid and pronounced increase in heart rate at low workloads, and subsequently after a return to sinus rhythm, where her heart rate response to exercise was in keeping with the expected chronotropic response. At both times, the patient was receiving therapeutic doses of oral digoxin.

In accordance with the Fick theorem, an interrelationship exists among cardiac output, arteriovenous O_2 difference and $\dot{V}O_2$. This relation is shown in Figure 5, where $\dot{V}O_2$ is expressed as isopleths of constant O_2 utilization for a 70-kg person of average body surface area (1.75 m^2), which permits us to convert the traditional expression of cardiac output in liter/min/m^2 to units of $\dot{V}O_2$, or ml/min/kg. From this relation it is apparent that irrespective of the rest cardiac output and arteriovenous O_2 difference, at peak exercise, when maximal O_2 extraction exceeds 70% (corresponding to the arteriovenous O_2 difference represented by the cross-hatched region in Figure 5), the aerobic capacity of the patient will be solely a function of cardiac output. Thus, for class D patients with a $\dot{V}O_2$ max of less than 10 ml/min/kg, maximal cardiac output will be 2 to 4 liters/min/m^2; in classes C, B and A it will be 4 to 6, 6 to 8 and >8 liters/min/m^2, respectively. Once again, the ability of the noninvasive determination of $\dot{V}O_2$ max to predict pump function and cardiac reserve is emphasized.

The response in arterial blood pressure from standing rest to maximal exercise is a function of the increment in cardiac output and the reduction in systemic vascular resistance. Figure 6 shows the response in systolic, mean and diastolic arterial pressures during upright treadmill exercise for each functional class. In class A patients, there is a normal increase in systolic and mean pressures

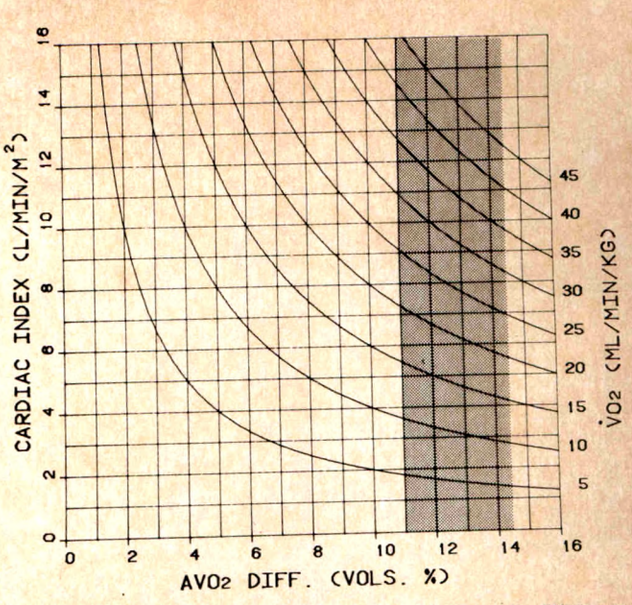

FIGURE 5. Relation among cardiac output, arteriovenous O_2 difference (AVO_2 DIFF) and O_2 uptake ($\dot{V}O_2$). In order to convert blood flow in liters/min/m^2 to ml/min/kg of $\dot{V}O_2$, blood flow data are expressed for a 70-kg person of average body surface area (1.75 m^2). **Cross-hatched area** for AVO_2 difference indicates maximum level of O_2 extraction for commonly observed levels of hemoglobin (i.e., 11 to 14 g/100 ml).

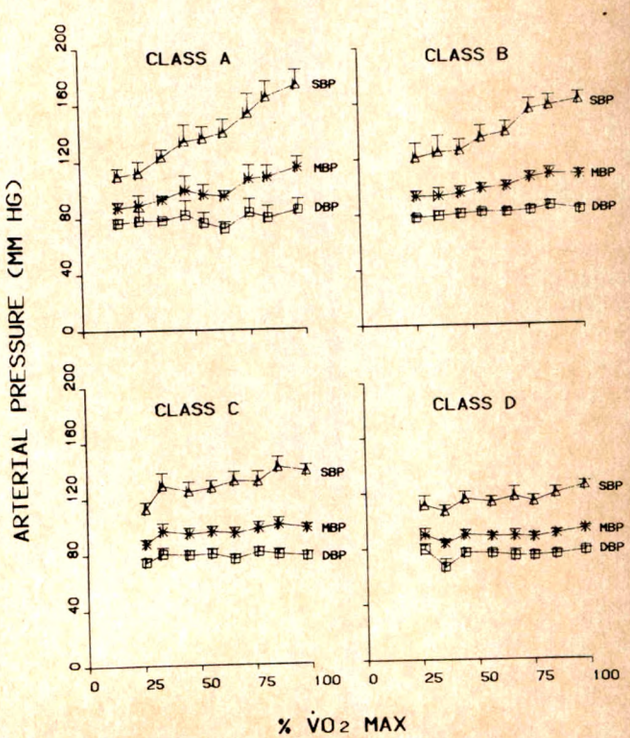

FIGURE 6. Response in arterial pressure (systolic [SBP], mean [MBP] and diastolic [DBP] pressures) for the 4 functional classes and according to level of aerobic work performed. Note attenuation of systolic blood pressure-response to exercise as functional capacity falls from class A to D. $\dot{V}O_2$ = O_2 uptake.

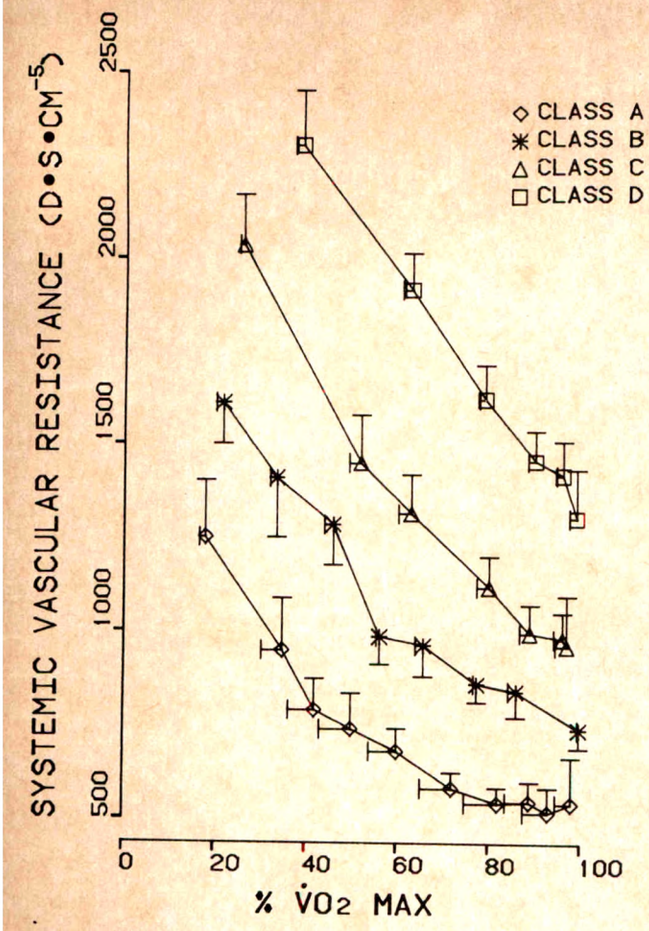

FIGURE 7. Response in calculated systemic vascular resistance from standing rest to maximal exercise for each functional class. In each class there is a progressive decrease in vascular resistance during exercise. $\dot{V}O_2$ MAX = maximal O_2 uptake.

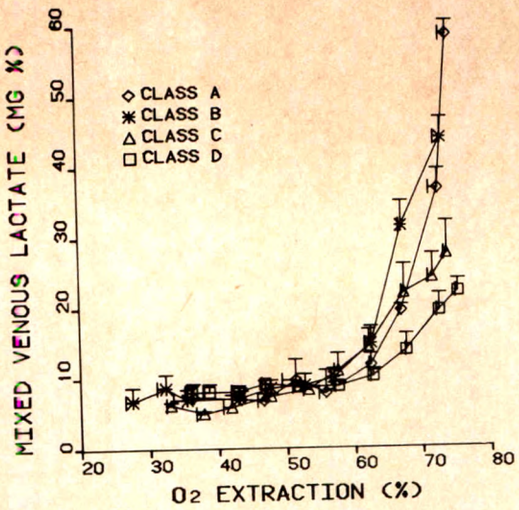
to 176 and 115 mm Hg, respectively, above the rest values (i.e., 115 and 91 mm Hg, respectively) as exercise reaches maximal levels; diastolic pressure remains unchanged throughout exercise, reflecting the progressive vasodilatation of working skeletal muscle. The blood pressure response of class B patients is not significantly different from that of class A patients. In contrast, the increase in systolic pressure is attenuated in class C and D patients. This is particularly evident in class D and is a function of the limited elevation in systemic blood flow in the face of skeletal muscle vasodilatation. None of the class C or D patients experienced lightheadedness or syncope during the exercise test or while recovering in the sitting position.

The decrease in systemic vascular resistance that occurs from standing rest to maximal exercise is shown in Figure 7. At rest, patients with minimal impairment (class A) differed significantly ($p < 0.05$) from patients in classes C and D, in whom a higher vascular resistance was the rule. During exercise, vascular resistance fell approximately 50% in each class. The minimal values of vascular resistance observed at maximum exercise, however, were significantly different ($p < 0.05$) among all but classes A and B. Even though the fall in resistance was similar in each class, the nonlinear relationship between resistance and cross-sectional area of circulation suggests that in patients with advanced CCF the degree of vasodilation of the skeletal muscle may be impaired as Zelis et al[27] have suggested.

Anaerobic threshold: Anaerobic muscle produces lactate. In our laboratory, the normal resting mixed venous lactate concentration is 7 to 8 mg%.[5] We assume that when mixed venous lactate concentration exceeds 12 mg%, which is 3 standard deviations above the average rest value, significant lactate production and release from anaerobic muscle is present. Figure 8, left, depicts the relation between mixed venous lactate concentration and O_2 extraction and the absolute level of $\dot{V}O_2$ attained during treadmill exercise. When systemic O_2 extraction exceeds 60%, lactate production is present. The appearance of anaerobiosis during exercise occurs at 60% or more of the aerobic capacity. Given the difference in aerobic capacity for each functional class, however, different workloads are required for each functional class to reach their anaerobic threshold (Fig. 8, right). In class D patients whose cardiac output response is limited, lactate production occurs at very light workloads requiring only 6 to 7 ml/min/kg of $\dot{V}O_2$ (e.g., 2 mets of work or walking down the corridor at a leisurely pace). In class C, a workload of 9 to 10 ml/min/kg is required before lactate production occurs. In classes B and A, higher loads are tolerated until lactate production occurs (i.e., 12 to 14 ml/min/kg and more than 14 ml/min/kg, respectively). Thus, the onset of anaerobiosis and the corresponding workload, or anaerobic threshold, reflect the severity of chronic cardiac failure. The differences in the absolute increase in mixed venous lactate observed in the classes may be related to differences in systemic and limb blood flow and the corresponding wash-out of lactate from working muscle.

We can noninvasively determine the anaerobic threshold in patients from their response in respiratory gas exchange during incremental treadmill exercise. We use several criteria for this purpose, as noted earlier. During the exercise test itelf, we monitor the temporal response in $\dot{V}O_2$ and $\dot{V}CO_2$ (Fig. 1 and 4), as well as the response in end tidal O_2 (Fig. 9). Consequently, we can immediately determine whether or not the patient has achieved an anaerobic level of work during the test. After the test we further analyze the response in gas exchange according to the criteria stated earlier and also illustrated in Figure 9. Matsumura et al[30] reported their findings regarding the noninvasive determination of anaerobic threshold during treadmill exercise in patients with CCF. Their observations are very similar to ours and support our view that the severity of CCF may be graded according to this measurement.

In summary, the incremental treadmill test, together with the noninvasive monitoring of respiratory gas exchange, heart rate and blood pressure provide two objective criteria, $\dot{V}O_2$ max and anaerobic threshold, by which the severity of CCF can be measured. The test is performed safely and easily by most patients, and is reproducible. If the underlying nature of the heart



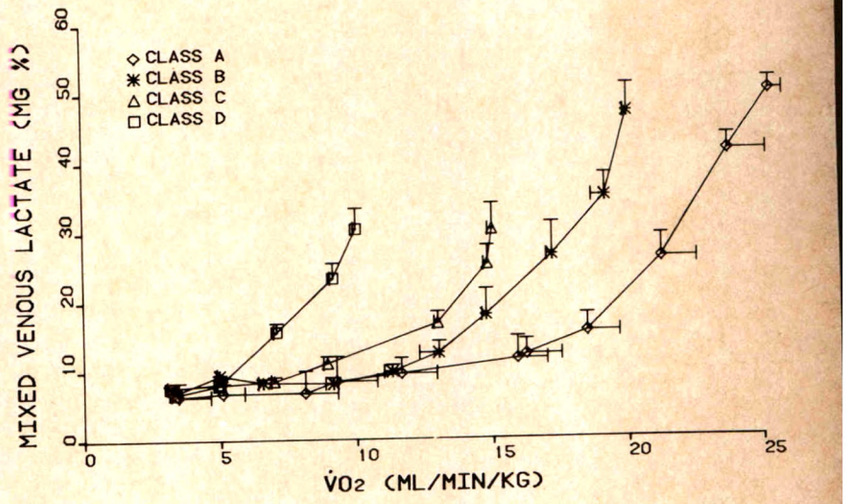


FIGURE 8. Response in mixed venous lactate concentration to exercise expressed as a function of O_2 extraction and level of work, or $\dot{V}O_2$, performed for each functional class. Lactate production (>12 mg%) occurs at different workloads and according to aerobic capacity.

disease is known, no additional testing is required, and the patient's exercise response can be followed serially to determine the natural course of the disease or the response to various therapeutic interventions. We chose this approach to examine the long-term efficacy of various pharmacologic agents in controlled clinical trials.[6–9] Patients receiving placebo in these trials, who were exercised serially over many months, did not alter their $\dot{V}O_2$ max or anaerobic threshold. These observations serve to indicate further the reproducibility of their exercise response.

Differentiating the cause of dyspnea in patients with coexistent heart and lung disease: Exertional dyspnea accompanies a wide variety of disorders, including heart disease, lung disease and pulmonary vascular disease. Many patients with CCF have coexistent obstructive or restrictive lung disease. In these patients it is difficult to identify whether or not the cause of breathlessness is due to heart or lung disease. Exercise testing can be used to elicit dyspnea and together with the measurement of respiratory gas exchange, air flow and ear oximetry aid in differentiating the cause of dyspnea.[8] Our approach is to obtain resting pulmonary function studies first, including measurement of MVV, FVC and peak expiratory flow rate. These data not only identify the ventilatory reserves from which the exercise response is drawn, but also aid in describing the severity of the underlying lung disease. During incremental isotonic exercise, we measure the tidal volume, respiratory rate, $\dot{V}_E$, expiratory flow rate and arterial O_2 saturation by ear oximeter while striving to have the patient reach his anaerobic threshold and $\dot{V}O_2$ max. The maximal tidal volume, maximum $\dot{V}_E$ and maximal flow rate obtained at the symptomatic endpoint to exercise are expressed as a fraction of the FVC, MVV and peak flow rate, respectively. In patients with CCF, and no underlying lung disease, these ratios rarely exceed 50%. Moreover, these patients can attain both their anaerobic threshold and $\dot{V}O_2$ max.[5] In patients with lung disease, in contrast, ventilatory response to exercise utilizes 70% or more of these reserves when the symptomatic endpoint to exercise is reached. Normal subjects also have difficulty sustaining a ventilatory effort above this level.[18,31] Additionally, although pa-

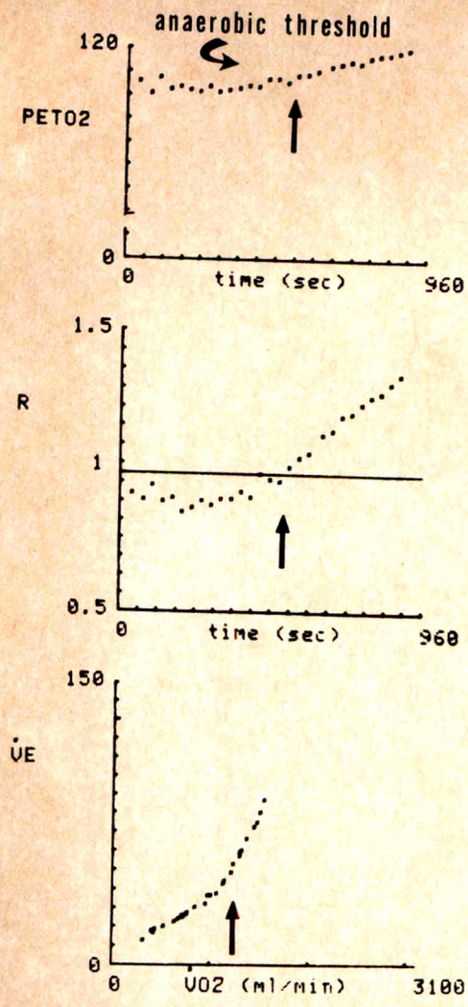

FIGURE 9. Noninvasive determination of anaerobiosis from response in end-tidal O_2 ($PETO_2$), respiratory gas exchange ratio (R) and minute ventilation ($\dot{V}_E$) relative to oxygen uptake ($\dot{V}O_2$) to incremental exercise for patient whose exercise response was given in Figure 1.

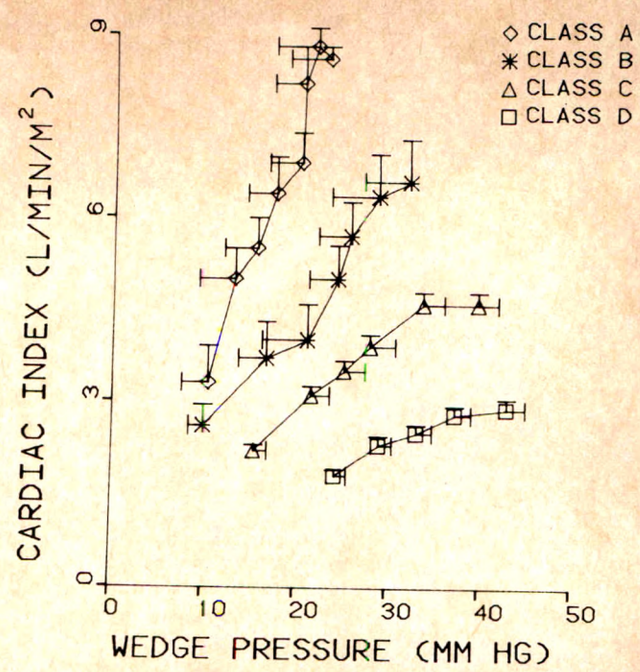

FIGURE 10. Response in ventricular function or elevation in cardiac output compared with left ventricular filling pressure, obtained from occlusive wedge pressure tracing at end expiration, from standing rest to maximal exercise for each functional class.

tients with lung disease may or may not reach their anaerobic threshold when they must stop exercising, they rarely if ever attain their $\dot{V}O_2$ max. Finally, patients with lung disease may demonstrate a fall in arterial O_2 saturation that is not seen in patients with ischemic or cardiomyopathic heart disease. Collectively, these responses aid in distinguishing the cause of exertional dyspnea.

The Invasive Exercise Test in Evaluating the Nature and Severity of Chronic Cardiac Failure

Hemodynamic monitoring: The information that can be obtained by invasive hemodynamic monitoring should be apparent from the foregoing discussion. In patients with CCF, a particular issue of interest is the response in occlusive wedge pressure during exercise. This information can aid in identifying the appearance of mitral regurgitation that is not present at rest. Such a finding may indicate why a patient with apparently adequate resting ventricular function has reduced aerobic capacity. The severity of mitral apparatus dysfunction secondary to a segmental wall motion abnormality or a myopathic process can be demonstrated from the elevation in pulmonary venous pressure that occurs during upright exercise. The relation between exercise cardiac output and and left ventricular filling pressure is given in Figure 10 for our 4 exercise classes. Class C and D patients have marked elevations in pulmonary venous pressure at rest and with any level of exercise, whereas in class B patients elevated wedge pressures develop only during exercise at higher workloads. In class D, the cardiac output response is inadequate despite these levels of filling pressure and indicates the severe impairment in myocardial contractile performance. Despite this pulmonary venous pressure, class C and D patients do not have clinical evidence of pulmonary congestion during or after the exercise test. This may be related to the transient nature of the elevation in pulmonary venous pressure given the limited effort tolerance of these patients, the enhanced lymphatic drainage of their lungs and the alterations in lung tissue pressure.

Acknowledgment: We deeply appreciate the dedicated and skillful technical expertise of Tom Nusbickel, without whom much of this work would not have been possible. We also acknowledge the assistance of David Ward and Stina Indovina in the preparation of this material.

Role of Vasodilators in the Treatment of Congestive Heart Failure

T. BARRY LEVINE, MD

Appreciation of the important role played by peripheral vasoconstriction in the pathophysiology of congestive heart failure (CHF) has led to the widespread use of vasodilators as treatment. Short-term studies show that, regardless of the vasodilator used, the arterial and venous dilatation produced invariably results in improvement in the hemodynamic status of patients. This short-term response, however, does not automatically translate to long-term clinical improvement. The reasons for this are not well understood but such factors as differing mechanisms of action, development of tolerance and unique patterns of regional redistribution of blood flow may all play a modifying role in differentiating one vasodilator from another. Nevertheless, a number of controlled trials have demonstrated sustained symptomatic and functional improvment when vasodilators such as the converting enzyme inhibitors or nitrates are given to patients with CHF.

(Am J Cardiol 1985;55:32A–35A)

Vasodilating agents are an accepted part of a comprehensive treatment regimen for patients with congestive heart failure (CHF). Their inclusion represents a realization of the important role played by the peripheral vasculature in the pathophysiology of heart failure.

Traditional therapy consists of administering digitalis to enhance myocardial contractility (thereby "reversing" the primary mechanical dysfunction) and diuretic drugs to rid the body of the excess salt and water build-up that accompany pump failure. While often effective in treating mild CHF, this approach does not consider the deleterious effects that peripheral vasoconstriction plays in further compromising the heart.

As pump function deteriorates and cardiac output decreases, a number of neurohumoral mechanisms (the sympathetic nervous system and renin-angiotensin system) are activated in order to maintain circulatory stability.[1] Arteriolar vasoconstriction results in an increased systemic vascular resistance, and venconstriction causes an increase in both venous return and left ventricular filling pressure. The normal heart, with an adequate reserve, can easily respond to the increase in aortic impedance by maintaining a normal cardiac output, or it can respond to an increase in preload by generating more systolic contractility and increasing stroke volume. Because the failing heart is on a much flatter Frank-Starling curve, increases in preload and afterload add to the heart's workload and further decrease pump function. This in turn activates more neurohumoral vasoconstriction, and thus a vicious cycle is established. Ventricular dysfunction is exacerbated by neurohumoral vasoconstrictor mechanisms and vice versa.

Therefore, the rationale for using vasodilators is to improve the working environment of the heart. Unlike inotropic agents, vasodilators have no direct action on left ventricular contractility, but function by reducing systemic vascular resistance (arteriolar vasodilatation) or left ventricular filling pressure (venodilatation) or both. This short-term hemodynamic effect can be seen in Figure 1, in which sodium nitroprusside was given to 47 patients with severe CHF. Pump function is made more efficient because of a decrease in workload and left ventricular filling. This results in an increase in cardiac output and a decrease in pulmonary pressure. Symptoms associated with either a low flow state or pulmonary congestion are therefore alleviated.

The theoretical appeal of using vasodilators to treat heart failure is reinforced by numerous studies demonstrating the beneficial short-term hemodynamic response to these agents. Yet there are differences among the various agents. Their mechanisms of action differ: some are direct vasodilators, such as sodium nitroprusside, nitrates, hydralazine and minoxidil; some are α_1-adrenergic blockers, such as prazosin and trimazosin;
